Chapter 11.6. *XDS*

W. Kabsch

11.6.1. Functional specification

The program package *XDS* (Kabsch, 1988*a*,*b*, 1993; Chapter 11.3) was developed for the reduction of single-crystal diffraction data recorded on a planar detector by the rotation method using monochromatic X-rays. It includes a set of three programs.

XDS accepts a sequence of adjacent non-overlapping rotation images from a variety of imaging-plate, charge-coupled-device (CCD), pixel and multiwire area detectors, infers crystal symmetry and metrics, and produces a list of corrected integrated intensities of the reflections occurring in the images in a nearly automatic way. The program assumes that each image covers the same positive amount of crystal rotation and that the rotation axis, incident beam and crystal intersect at one point, but otherwise imposes no limitations on the detector position, on the directions of the rotation axis and incident beam or on the oscillation range covered by each image.

XSCALE places the data sets obtained from processing with *XDS* on a common scale, optionally merges them into one or several sets of unique reflections and reports their completeness and the quality of the integrated intensities. It corrects the data for absorption effects, sensitivity variations in the detector plane and radiation damage. Optionally, it can correct reflections individually for radiation damage by extrapolation to their initial intensities at zero dose.

XDSCONV converts reflection data files as obtained from *XDS* or *XSCALE* into various formats required by software packages for crystal structure determination. It can generate test reflections or inherit previously selected ones which are used for the calculation of a free R factor to monitor the progress of structure refinement.

11.6.2. *XDS*

XDS is organized into eight steps (major subroutines) which are called in succession by the main program. Information is exchanged between the steps by files (see Table 11.6.2.1), which allows the repetition of selected steps with a different set of input parameters without rerunning the whole program. The files generated by *XDS* are either ASCII-type files that can be inspected and modified using a text editor, or binary control images saved as a byte-offset variant of the CBFlib format (Bernstein & Hammersley, 2005; Bernstein & Ellis, 2005). Such images are indicated by the file-name extension `.cbf` and can be looked at using the open-source program *XDS-Viewer* written by Michael Hoffer.

All files have a fixed name defined by *XDS*, which makes it mandatory to process each data set in a newly created directory in order to avoid name clashes. Clearly, one should not run more than one *XDS* job at a time in the same directory. Output files affected by rerunning selected steps (see Table 11.6.2.1) should also first be given another name if their original contents are meant to be saved.

Data processing begins by copying an appropriate input file into the new directory. Input-file templates are provided with the *XDS* package for a number of frequently used data-collection facilities. The copied input file must be renamed `XDS.INP` and edited to provide the correct parameter values for the actual data-collection experiment. All parameters in `XDS.INP` are named by keywords containing an equals sign as the last character and many of them will be mentioned here in context in order to clarify their meaning. Execution of *XDS* (JOB=XDS) invokes each of the eight program steps as described below. The results and diagnostics from each step are saved in files with the extension `.LP` attached to the program-step name. These files should always be studied carefully to see whether processing was satisfactory or, in the case of failure, to find out what could have gone wrong.

11.6.2.1. *XYCORR*

This program step calculates a lookup table of additive spatial corrections at each detector pixel which is stored in the files `X-CORRECTIONS.cbf`, `Y-CORRECTIONS.cbf`. Often, the data images have already been corrected for geometrical distortions, in which case *XYCORR* produces tables of zeros.

For spiral read-out imaging-plate detectors the small corrections resulting from radial (ROFF=) and tangential (TOFF=) offset errors of the scanner are computed.

For some multiwire and CCD detectors that deliver geometrically distorted images, corrections are derived from a calibration image (BRASS_PLATE_IMAGE=file name). This image displays the response to a brass plate containing a regular grid of holes which is mounted in front of the detector and illuminated by an X-ray point source. Clearly, the source must be placed exactly at the location to be occupied by the crystal during the actual data collection, as photons emanating from the calibration source are meant to simulate all possible diffracted beam directions. For visual control, spots that have been located and accepted from the brass-plate image by *XYCORR* are marked in the file `FRAME.cbf`.

The following problems can be encountered in this step.

(i) A misplaced calibration source can lead to an incorrect lookup table, impairing the correct prediction of the observed diffraction pattern in subsequent program steps.
(ii) An underexposed calibration image can result in an incomplete and unreliable list of calibration spots.

11.6.2.2. *INIT*

INIT determines three lookup tables, saved as the files `BLANK.cbf`, `GAIN.cbf` and `BKGINIT.cbf`, that are required by the subsequent processing steps for classifying pixels in the data images as background or belonging to a diffraction spot ('strong' pixels). These tables should be inspected with the *XDS-Viewer* program.

`BLANK.cbf` contains a lookup table of the detector noise. It is determined from a specific image recorded in the absence of X-rays (DARK_CURRENT_IMAGE=) or is assumed to be a constant derived from the mean recorded value in each corner of the data images.

GAIN.cbf codes for the expected variation of the pixel contents in the background region of a data image. The variance of the contents of a pixel in the background region is GAIN·(pixel contents − detector noise). The variance is determined from the scatter of pixel values within a rectangular box (NBX=, NBY=) of size (2·NBX + 1)·(2·NBY + 1) centred at each image pixel in succession. The table GAIN.cbf is used to distinguish background pixels from 'strong' pixels that are part of a diffraction spot.

BKGINIT.cbf estimates the initial background at each pixel from a few data images specified by the input parameter BACKGROUND_RANGE=. The lookup table is obtained by adding the X-ray background from each image. Shaded regions on the detector (*i.e.* from the beamstop), pixels outside a user-defined circular region (TRUSTED_REGION=) or pixels with an undefined spatial correction value are classified as untrustworthy and marked by −3.

The following problem can be encountered in this step. Some detectors with insufficient protection from electromagnetic pulses may generate badly spoiled images whose inclusion leads to a completely wrong X-ray background table. These images can be identified in INIT.LP by their unexpected high mean pixel contents and this step should be repeated with a different set of images.

11.6.2.3. *COLSPOT*

COLSPOT locates strong diffraction spots occurring in a subset of the data images and saves their centroids in the file SPOT.XDS. The data subset is defined by contiguous image number ranges, where each range is specified by the keyword SPOT_RANGE=. As described in Chapter 11.3, spots are defined as sets of 'strong' pixels that are adjacent in three dimensions. The classification of 'strong' pixels is controlled by the decision constants STRONG_PIXEL= and BACKGROUND_PIXEL=. If the total number of 'strong' pixels occurring in the specified data images exceeds the upper limit as given by the input parameter MAXIMUM_NUMBER_OF_STRONG_PIXELS=, the weaker ones are discarded. A spot is accepted if it contains a minimum number of 'strong' pixels (MINIMUM_NUMBER_OF_PIXELS_IN_A_SPOT=) and if the spot centroid is sufficiently close to the location of the strongest pixel in the spot (SPOT_MAXIMUM-CENTROID=).

The following problem can be encountered in this step. Sharp edges such as ice rings in the images can lead to an excessive number of 'strong' pixels being erroneously classified as contributing to diffraction spots. These aliens could prevent *IDXREF* from recognizing the crystal lattice.

11.6.2.4. *IDXREF*

IDXREF uses the initial parameters describing the diffraction experiment as provided by XDS.INP and the observed centroids of the spots from the file SPOT.XDS to find the orientation, metric and symmetry of the crystal lattice, and refines all or a specified subset of these parameters [input parameter REFINE(IDXREF)=] . On return, the complete set of parameters are saved in the file XPARM.XDS and the original file SPOT.XDS is replaced by a file of identical name, now with indices attached to each observed spot. Spots not belonging to the crystal lattice are given indices 0, 0, 0. *XDS* considers the run to be successful if the coordinates of at least 70% of the given spots can be explained with reasonable accuracy (input parameter MAXIMUM_ERROR_OF_SPOT_POSITION=); otherwise, *XDS* will stop with an error message. Alien spots often arise because of the presence of ice or small satellite crystals and continuation of data processing may still be meaningful. In this case, *XDS* is called again with an explicit list of the subsequent steps specified in XDS.INP (input parameter JOB=DEFPIX XPLAN INTEGRATE CORRECT).

IDXREF uses the methods described in Kabsch (1993; Chapter 11.3) to determine a crystal lattice that explains the observed locations of the diffraction spots listed in the file SPOT.XDS. Firstly, a reciprocal-lattice vector referring to the unrotated crystal is computed from each observed spot centroid. Differences between any two reciprocal-lattice vectors that are above a specified minimal length (SEPMIN=) are accumulated in a three-dimensional histogram. These difference vectors will form clusters in the histogram, since there are many different pairs of reciprocal-lattice vectors of nearly identical vector difference. The clusters are found as maxima in the smoothed histogram (CLUSTER_RADIUS=) and a basis of three linearly independent cluster vectors is selected that allows all other cluster vectors to be expressed as nearly integral multiples of small magnitude with respect to this basis. The basis vectors and the 60 most populated clusters with attached indices are listed in `IDXREF.LP`. If many of the indices deviate significantly from integral values, the program is unable to find a reasonable lattice basis and all further processing will be meaningless.

If the space group and unit-cell parameters are specified, a reduced cell is derived and the reciprocal-basis vectors found above are reinterpreted accordingly; otherwise, a reduced cell is determined directly from the reciprocal basis. The parameters of the reduced cell, the coordinates of the reciprocal-basis vectors and their indices with respect to the reduced cell are reported.

Based on the orientation and metric of the reduced cell now available, *IDXREF* indexes up to 3000 of the strongest spots using the local-indexing method. This method considers each spot as a node of a tree and identifies the largest subtree of nodes which can be assigned reliable indices. The number of reflections in the ten largest subtrees is reported and usually shows a dominant first tree corresponding to a single lattice, whereas alien spots are found in small subtrees. Reflections in the largest subtree are used for initial refinement of the basis vectors of the reduced cell, the incident-beam wavevector and the origin of the detector, which is the point in the detector plane nearest to the crystal. Experience has shown that the detector origin and the direction of the incident beam are often specified with insufficient accuracy, which could easily lead to a misindexing of the reflections by a constant offset. For this reason, *IDXREF* considers alternative choices for the index origin and reports their likelihood of being correct. The parameters controlling the local indexing are INDEX_ERROR=, INDEX_MAGNITUDE=, INDEX_QUALITY= (corresponding to ε, φ and $1 - \ell_{\min}$ in Chapter 11.3) and INDEX_ORIGIN=h_0, k_0, l_0, which is added to the indices of all reflections in the tree. After initial refinement based on the reflections in the largest subtree, all spots which can now be indexed are included. Usually, the detector distance and the direction of the rotation axis are not refined, but if the spots were extracted from images covering a large range of total crystal rotation then better results are obtained by including these parameters in the refinement [REFINE(IDXREF)=] .

The refined metric parameters of the reduced cell are used to test each of the 44 possible lattice types as described in Chapter 11.3. For each lattice type, *IDXREF* reports the likelihood of its being correct and the conventional unit-cell parameters. The program step concludes with an overview of possible lattice symmetries, but makes no automatic decision for the space group. If the crystal symmetry is unknown, *XDS* will continue data processing with the crystal being described by its reduced-cell basis vectors and triclinic symmetry. Space-group assignment is postponed to the last program step, *CORRECT*, when integrated intensities are available.

The following problems can be encountered in this step.

(i) The indices of many difference-vector clusters deviate significantly from integral values. This can be caused by incorrect input parameters, such as rotation axis, oscillation angle or detector position, by a large fraction of alien spots in `SPOT.XDS`, by placing the detector too close to the crystal or by an inappropriate choice of the parameters SEPMIN= and CLUSTER_RADIUS= in densely populated images.

(ii) Indexing and refinement is unsatisfactory despite well indexed difference-vector clusters. This is probably caused by the selection of an incorrect index origin and *IDXREF* should be rerun with plausible alternatives for INDEX_ORIGIN= after a visual check of a data image with *XDS-Viewer*.

(iii) Despite successful indexing and refinement, *IDXREF* stops with the error message INSUFFICIENT PERCENTAGE OF INDEXED REFLECTIONS, complaining that less than 70% of the given spots could be explained. Alien spots often arise because of the presence of ice or small satellite crystals and continuation of data processing may still be meaningful. To continue data processing, just specify the missing processing steps in `XDS.INP` by JOB=DEFPIX XPLAN INTEGRATE CORRECT and call *XDS* again.

11.6.2.5. DEFPIX

DEFPIX recognizes regions in the initial background table (file `BKGINIT.cbf`) that are obscured by intruding hardware and marks the shaded pixels as untrusted. In addition, pixels that are outside a user-defined resolution range (INCLUDE_RESOLUTION_RANGE=) are marked and eliminated from the trusted region. The marked background table that is thus obtained is saved in the file `BKGPIX.cbf`, which is needed by the subsequent program steps. To recognize the obscured regions in the initial background, *DEFPIX* generates a control image (file `ABS.cbf`) that contains values of around 10 000 for unshaded pixels and lower values for shaded pixels. The classification of the pixels into reliable and untrusted pixels is based on the two input parameters VALUE_RANGE_FOR_TRUSTED_DETECTOR_PIXELS= (default 6000 30 000) and INCLUDE_RESOLUTION_RANGE= (default 20.0 0.0). Pixels in the table `ABS.cbf` with a value outside the ranges specified by the two parameters are marked unreliable (by −3) in the background table `BKGPIX.cbf`.

The following problem can be encountered in this step. If the parameter VALUE_RANGE_FOR_TRUSTED_DETECTOR_PIXELS= specifies a value range that is too narrow, ‘good’ regions will erroneously be excluded from the trusted detector region. Check `BKGPIX.cbf` with the *XDS-Viewer* program and if necessary repeat the *DEFPIX* step with more appropriate values.

11.6.2.6. XPLAN

XPLAN supports the planning of data collection. It is based upon information provided by the input files `XPARM.XDS` and `BKGPIX.cbf`, both of which become available on processing a few test images with *XDS*. *XPLAN* estimates the completeness of new reflection data expected to be collected for each given starting angle and total crystal rotation and reports the results for a number of selected resolution shells in the file `XPLAN.LP`. To minimize the recollection of data, the name of a file containing already measured reflections can be provided by the input parameter REFERENCE_DATA_SET=.

The following problems can be encountered in this step.

(i) Incorrect results may occur for some space groups, *i.e.* $P4_2$, if the unit cell determined by *XDS* from processing a few test images implicates reflection indices that are inconsistent with those from the reference data set. However, the correct cell choice can be found by using the old data as a reference and repeating *CORRECT* with the appropriate reindexing transformation, followed by copying `GXPARM.XDS` to `XPARM.XDS`. The same applies if *IDXREF* was run for an unknown space group and then reindexed in *CORRECT*.

(ii) *XPLAN* ignores potential reflection overlap owing to the finite oscillation range covered by each image.

11.6.2.7. INTEGRATE

INTEGRATE determines the intensity of each reflection predicted to occur in the rotation data images (DATA_RANGE=) and saves the results in the file `INTEGRATE.HKL`.

The diffraction parameters needed to predict the reflection positions are initially provided by the file `XPARM.XDS`. These parameters are either kept constant or refined periodically using strong diffraction spots encountered in the data images. Whether refinement should be carried out at all and which parameters are to be refined can be specified by the user [input parameter REFINE(INTEGRATE)=]. The centroids of the strong spots in the data images are computed from pixels that exceed the background by a given multiple of standard deviations (input parameters SIGNAL_PIXEL=, BACKGROUND_PIXEL=). Strong spots are used in the refinement if their centroids are reasonably close to their calculated position (input parameter MAXIMUM_ERROR_OF_SPOT_POSITION=).

For determination of the intensity, approximate values describing the extension and the form of the diffraction spot must be specified. The shapes of all spots become very similar when the contents of each of their contributing image pixels are mapped onto a three-dimensional coordinate system, specific for each reflection, which has its origin on the surface of the Ewald sphere at the terminus of the diffracted beam wavevector (see Chapter 11.3). The transformed spot can roughly be described as a Gaussian involving two parameters: the standard deviations of the reflecting range σ_M (input parameter REFLECTING_RANGE_E.S.D.=σ_M) and the beam divergence σ_D (input parameter BEAM_DIVERGENCE_E.S.D.=σ_D). This leads to an integration region around the spot that is defined by the parameters δ_M (REFLECTING_RANGE=) and δ_D (BEAM_DIVERGENCE=), which are typically chosen to be 6–10 times larger than σ_M and σ_D, respectively. Appropriate values for these parameters are determined automatically by *XDS* (Chapter 11.3); the user has the option to override the automatic assignments.

Integration is carried out by a two-step procedure. In the first pass, spot templates are generated by superimposing the profiles of strong reflections after their mapping to the Ewald sphere. Grid points with a value above a minimum percentage of the maximum in the template (parameter CUT=) are marked for inclusion in the final integration. To allow for variations in their shape, profile templates are generated from reflections located at nine regions of equal size covering the detector surface and additional sets of nine to cover equally sized (parameter DELPHI=) batches of images. The actual integration is carried out in the second pass by profile fitting with respect to the spot shape determined in the first pass. Incomplete reflections below a minimum percentage of the observed reflection intensity (parameter MINPK=) will be discarded. Otherwise, the missing intensity is estimated from the learned reflection profiles.

On return from the *INTEGRATE* step, all spots expected to occur in the last data image are encircled and the modified image is saved as the file `FRAME.cbf` for inspection.

The following problems can be encountered in this step.

(i) Off-centred profiles indicate incorrectly predicted reflection positions by using the parameters provided by the file `XPARM.XDS` (*i.e.* misindexing by using a wrong origin of the indices), crystal slippage or change in the incident-beam direction.

(ii) Profiles extending to the borders of the box indicate too-small values of the parameters BEAM_DIVERGENCE= or REFLECTING_RANGE=. This leads to incorrect integrated intensities because of truncated reflection profiles and unreliable background determination.

(iii) Display of the file `FRAME.cbf` shows spots which are not encircled. If these unexpected reflections are not close to the spindle and are not ice reflections, then it is likely that the parameters provided by the file `XPARM.XDS` are wrong.

11.6.2.8. CORRECT

CORRECT applies correction factors to the intensities and standard deviations of all reflections found in the file `INTEGRATE.HKL`, determines the space group if unknown and refines the unit-cell parameters, reports the quality and completeness of the data set and saves the final integrated intensities in the file `XDS_ASCII.HKL`. Some of the employed algorithms are new and are described in Chapter 11.3.

CORRECT accepts reflections from the file `INTEGRATE.HKL` that are

(i) recorded (parameter MINPK=) on specified images (parameter DATA_RANGE=);

(ii) within a given resolution range (parameter INCLUDE_RESOLUTION_RANGE=);

(iii) outside ice rings (parameter EXCLUDE_RESOLUTION_RANGE=);

(iv) not overloaded (parameter OVERLOAD=); and

(v) not marked for exclusion in the file `REMOVE.HKL`.

Thus, the user has the option to exclude unreliable reflections from the final data set by repeating the *CORRECT* step with appropriate parameter values.

The intensities of the accepted reflections are first corrected for effects arising from polarization of the incident beam (parameters FRACTION_OF_POLARIZATION=, POLARIZATION_PLANE_NORMAL=) and absorption effects (parameters AIR=, SILICON=, SENSOR_THICKNESS=) arising from differences in path lengths of the diffracted beam. These corrections do not depend on knowledge of the space group.

The integrated intensities of the reflections in the file `INTEGRATE.HKL` may or may not have been indexed in the correct space group; for the purpose of integration, it is important only that all reflections occurring in the data images have been indexed with respect to some unit-cell basis and that their locations on the images were hit exactly. The correct reflection indices in the true space group are always a linear transformation of the original indices used in `INTEGRATE.HKL`. All lattices consistent with the locations of the reflections saved in `INTEGRATE.HKL` (decision parameters MAX_CELL_AXIS_ERROR=, MAX_CELL_ANGLE_ERROR=) and their corresponding linear transformations are printed to provide a useful overview similar to that shown in `IDXREF.LP`.

If the space group is not specified, *XDS* proposes one of the enantiomorphous space groups without screw axes that is compatible with the observed lattice symmetry and explains the intensities of a subset of the reflections (parameter TEST_RESOLUTION_RANGE=) at an acceptable $R_{\rm meas}$ (Diederichs & Karplus, 1997; Weiss, 2001) using a minimum number of unique reflections. The criteria for an acceptable $R_{\rm meas}$ are controlled by the decision parameters MIN_RFL_Rmeas= and MAX_FAC_Rmeas=.

The user can always override the automatic decisions by specifying the correct space-group number (parameter SPACE_GROUP_NUMBER=) and unit-cell parameters (parameter UNIT_CELL_CONSTANTS=) in `XDS.INP` and repeating the *CORRECT* step. This provides a simple way to rename orthorhombic unit-cell parameters, which often becomes necessary if screw axes are present. In addition, the user has the option to specify the following in `XDS.INP`:

(i) a reference data set (parameter REFERENCE_DATA_SET=),
(ii) a reindexing transformation (parameter REIDX=) and
(iii) three basis vectors if known from processing a previous data set taken at the same crystal orientation in a multi-wavelength experiment (parameters UNIT_CELL_A-AXIS=, UNIT_CELL_B-AXIS=, UNIT_CELL_C-AXIS=).

The possibility of comparing the new data with a reference data set is particularly useful for resolving the issue of alternative settings of polar or rhombohedral cells (such as $P4$, $P6$ and $R3$). Also, reference data are quite useful for recognizing misindexing or for testing potential heavy-atom derivatives.

For refinement of the unit-cell parameters [parameter REFINE(CORRECT)=], *CORRECT* uses a subset of the accepted reflections whose observed centroid is sufficiently close to the predicted spot position (parameter MAXIMUM_ERROR_OF_SPOT_POSITION=). The refined set of parameters is saved in the file `GXPARM.XDS`, which has an identical layout to the file `XPARM.XDS` produced by *IDXREF*. If the crystal has not slipped during data collection, these parameters are quite accurate.

Other correction factors (parameter CORRECTIONS=) which partially compensate for radiation damage, absorption effects and variations in the sensitivity of the detector surface are determined from the symmetry-equivalent reflections usually found in the data images. The corrections are chosen such that the integrated intensities of symmetry-equivalent reflections come out as similar as possible. The user may control application of the various corrections by specifying the parameter CORRECTIONS= by a combination of the keywords DECAY MODULATION ABSORPTION. Whether Friedel pairs are considered as symmetry-equivalent reflections in the calculation of the correction factors depends on the values of the two parameters STRICT_ABSORPTION_CORRECTION= and FRIEDEL'S_LAW=. The number of correction factors is controlled by the input parameters MINIMUM_I/SIGMA=, NBATCH= and REFLECTIONS/CORRECTION_FACTOR=.

The residual scatter in intensity of symmetry-equivalent reflections is used to estimate their standard deviations. Here, the initial estimate $v_0(I)$ (obtained from the *INTEGRATE* step) for the variance of the reflection intensity I is replaced by $v(I) = a[v_0(I) + bI^2]$. The two constants a and b are chosen to minimize discrepancies between $v(I)$ and the variance estimated from sample statistics of symmetry-related reflections. Based on the more realistic error estimates for the intensities, outliers are recognized by comparison with other symmetry-equivalent reflections. These outliers are included in the main output file `XDS_ASCII.HKL`, in which they are marked by a negative sign attached to the estimated standard deviations of their intensity. Classification of a reflection as a misfit is controlled by a decision constant which has the default value of WFAC1=1.5. Specification of a lower value such as WFAC1=1.0 by the user will lead to an increasing number of misfits and lower R factors as outliers are not included in the reported statistics.

Data quality as a function of resolution is described by the agreement of intensities of symmetry-related reflections and quantified by the R factors $R_{\rm merge}$ and the more robust indicator $R_{\rm meas}$ (Diederichs & Karplus, 1997; Weiss, 2001). These R factors as well as the intensities of all reflections with indices of type $h00$, $0k0$ and $00l$ and those expected to be systematically absent provide important information for identification of the correct space group. Clearly, large R factors or many rejected reflections or large observed intensities for reflections that are expected to be systematically absent suggest that the assumed space group or indexing is incorrect. The presence or absence of anomalous scatterers is specified by the parameter FRIEDEL'S_LAW=. Finally, *CORRECT* analyzes the distribution of reflection intensities as a function of their resolution and reports outliers from the Wilson plot. Often, these aliens arise from ice rings in the data images. To suppress the unwanted reflections from the final output file `XDS_ASCII.HKL`, the user copies them to a file named `REMOVE.HKL` in the current directory and repeats the *CORRECT* step.

The following problems can be encountered in this step.

(i) Incomplete data sets may lead to wrong conclusions about the space group, as some of its symmetry operators might not be involved in the R-factor calculations.
(ii) Often, the *CORRECT* step is repeated several times. It should be remembered that *XDS* overwrites earlier versions of the output files `XDS_ASCII.HKL`, `GXPARM.XDS` *etc.*

11.6.3. *XSCALE*

The scaling program *XSCALE*

(i) puts one or more files obtained from data processing with *XDS* on a common scale and reports the completeness and quality of the data sets;
(ii) offers a choice of either combining symmetry-equivalent observations into a single unique reflection or saving the scaled but unmerged observations in the output file;
(iii) allows several output files that are placed on the same scale, a feature that is recommended for multiwavelength anomalous diffraction (MAD) data sets taken from the same crystal at different wavelengths;
(iv) determines correction factors that partially compensate for absorption effects, sensitivity variations in the detector plane and radiation damage; and
(v) can correct reflections individually for radiation damage (Diederichs *et al.*, 2003).

The program uses a new fast algorithm (Chapter 11.3) and imposes no limitations on the number of data sets or scaling/correction factors. The easiest way to run *XSCALE* is to copy a template input file named `XSCALE.INP` to a new directory and to replace the parameter values by the appropriate values describing the actual scaling run. The input parameters may be given in arbitrary order, except for the parameters defining the input and output reflection files (INPUT_FILE=, OUTPUT_FILE=). Here, an output file is defined first by the parameter OUTPUT_FILE= that will include the scaled and merged reflections from all following input files specified by the parameters INPUT_FILE= until the next occurrence of OUTPUT_FILE= in `XSCALE.INP`. An arbitrary number of output files can be specified (together with their set of input files) in a single run of *XSCALE*. All output files are then on the same scale, which is a useful program feature for MAD data sets.

The reflections in each output file will be unmerged and Friedel pairs will be considered to be different if this holds for all of the input data sets unless explicitly redefined by the parameters MERGE= and FRIEDEL'S_LAW=. Moreover, each output file accepts an additional parameter that controls how the Friedel pairs of the input files are treated in the calculation of the absorption correction factors. If STRICT_ABSORPTION_CORRECTION=FALSE, Friedel pairs are treated as symmetry-equivalent reflections in these calculations, which could lead to an underestimate of the anomalous differences in the presence of anomalous scatterers. Friedel pairs are only treated as different reflections in the calculations if STRICT_ABSORPTION_CORRECTION=TRUE and FRIEDEL'S_LAW=FALSE.

For each input file, a resolution window for accepting reflections (INCLUDE_RESOLUTION_RANGE=), the extent of absorption corrections (CORRECTIONS=DECAY MODULATION ABSORPTION) and the number of correction factors (NBATCH=) can be specified. Finally, each input data set can be corrected for radiation damage by specifying the name of the crystal the data set was obtained from (CRYSTAL_NAME=). Specification of this parameter implicates zero-dose extrapolation of individual reflection intensities to compensate for the effects of radiation damage experienced by the crystal so far (see Diederichs *et al.*, 2003).

Each resulting scaled data set is of XDS_ASCII format. It can be converted into a CCP4-style multi-record MTZ file using the copy feature of the program *POINTLESS* (Evans, 2006) available from the web (ftp://ftp.ccp4.ac.uk/ccp4/6.0.2/prerelease/pointless.html) or converted by *XDSCONV* into the format required by various structure-solution packages.

11.6.4. *XDSCONV*

XDSCONV accepts reflection-intensity data files as produced by *XSCALE* or *CORRECT* and converts them into the format required by software packages for structure determination. *XDSCONV* estimates structure-factor moduli based on the assumption that the intensity data set obeys Wilson's distribution and uses a Bayesian approach to statistical inference as described by French & Wilson (1978). The output file generated may inherit the test reflections previously used to calculate a free *R* factor (Brünger, 1992) or may contain new test reflections selected by *XDSCONV*.

11.6.5. Parallelization of *XDS*

In order to efficiently use modern multiprocessor hardware, a major effort has been undertaken to replace the original code of *XDS* by routines that can run concurrently with very little need for synchronization. As described above, data processing by *XDS* is organized into eight steps that must be executed in a fixed order since the result of each step is needed as input for the subsequent ones. Thus, the only way to speed up processing is to make each step faster.

The most computationally intensive steps are *COLSPOT* and *INTEGRATE* and, to a lesser degree, the routine that refines diffraction parameters in *IDXREF* and *CORRECT*. Thus, the highest savings in wall clock time are expected to result from changing these routines so that each one can make efficient use of the multiprocessor hardware. Two methods can be used (simultaneously) to speed up data processing.

In the first method, *XDS* divides the set of data images into approximately equal portions, calls a shell script that starts an independent job for processing each portion of images by the computer cluster and waits until all jobs have finished. The number of such independent jobs can be limited by the user (MAXIMUM_NUMBER_OF_JOBS=); up to 99 jobs are allowed. This method works even if the processors do not share the same address space, since the jobs are independent processes that do not communicate at all.

The second method uses OpenMP to control execution by a team of threads and relies on a shared-memory multiprocessor platform. This allows the program to exploit data parallelism at a more fine-grained level to speed up refinements and routines for setting up and solving systems of linear equations. The maximum number of threads that can be employed by the parallel version of *XDS* (xds_par, xscale_par) can be limited by the user (MAXIMUM_NUMBER_OF_PROCESSORS=); up to 32 processors can be used. OpenMP has been chosen for execution control because it hardly adds to the complexity of the program code and most importantly does not require the maintenance of separate versions of the source code depending on whether the program is intended for execution by a team of processors or just by a single CPU. Moreover, OpenMP has become the *de facto* standard and compilers accepting OpenMP directives are available for most shared-memory multiprocessor platforms.

The new version of *COLSPOT* comprises an initial part, a concurrent procedure and a final part. After initialization each available processor is kept busy analysing its share of rotation images for strong pixels, which are saved in a processor-specific file. In the final sequential part of *COLSPOT* all files resulting from the concurrent computations are read and the location addresses, image running numbers and signal values of the strong pixels are stored in a hash table. Strong pixels belonging to the same spot can be located rapidly in this table and the centroids of the spots are saved in the final output file from this step.

For the *INTEGRATE* step, the rotation images are divided into approximately equal portions for independent processing under control by a shell script according to the first method described above. When all jobs have finished, the integrated intensities from each independent file are joined. Minor problems could occur for reflections that receive intensity contributions from images that have been processed by different jobs. Compared with processing as a single job, the observed intensity differences are small and disappear if the different jobs use identical reference profiles and diffraction parameters to predict spot locations [to avoid refinements, specify REFINE(INTEGRATE)=!].

In addition, each of the independent jobs can be executed by a team of processors controlled by OpenMP. The rotation images analysed by each job are split into a sequence of batches of consecutive images that cover a total rotation range that is large enough to accommodate the integration domain. The batches are evaluated in strictly sequental order; parallel processing is confined to images within each batch.

The restructured routine for the *INTEGRATE* step consists of code regions for parallel execution interspersed by sequential sections. After initialization, strong reflections and their mean size and extent are determined concurrently. The diffraction parameters are refined in parallel-processing mode based on the observed spot locations. In the following sequential section a database is generated containing information about all reflections occurring in this batch of images. A subset of strong reflections is also identified that is useful for the subsequent reflection-profile learning pass. The mean profile of these reflections is determined concurrently in a second pass through the images in the batch. Reflection integration by profile fitting is carried out in parallel in the third cycle through the batch. In the final sequential step the results from each job, which have been saved in files, are harvested and intensity contributions to the same reflection from adjacent batches are merged.

11.6.6. Availability

Documentation and executable versions of the *XDS* package for widely used computer systems running under Linux or OSX can be obtained from the *XDS* homepage (http://xds.mpimf-heidelberg.mpg.de/) free of charge for use by academics for noncommercial applications. Additional information can be found at http://strucbio.biologie.uni-konstanz.de/xdswiki/index.php/XDS.

For looking at rotation data images and control images generated by *XDS*, an open-source program *XDS-Viewer* written by Michael Hoffer can be obtained from http://xds-viewer.sourceforge.net under the GNU General Public License.

A graphical interface *XDSi* (Kursula, 2004) is available (http://cc.oulu.fi/~pkursula/xdsi.html) that simplifies the operation of *XDS*.

This chapter is based on a recent article published in *Acta Crystallographica Section D* (Kabsch, 2010).

Chapter 11.7. Detecting twinning by merohedry

T. O. Yeates and Y. Tsai

11.7.1. Introduction

Twinning is a growth disorder in which different regions or domains of a crystal specimen are oriented differently with respect to each other (reviewed in Yeates, 1997; Dauter, 2003; Parsons, 2003; Helliwell, 2008). Numerous types of twinning are possible and a hierarchy among the types has been articulated (Yeates & Fam, 1999) (Fig. 11.7.1.1). In the most general type, differently oriented twin domains in the crystal have lattices that are distinguishable from each other. As a result, the different domains are associated with distinct reciprocal lattices and therefore with distinguishable interpenetrating diffraction patterns. This type of twinning is therefore generally recognized in X-ray diffraction images. The situation is referred to as twinning by non-merohedry and has also been referred to occasionally in the literature as 'epitaxial twinning'. However, the latter term is usually used to describe the growth of a crystal of heterogeneous molecules. Treatment of twinning by non-merohedry usually amounts to a data-collection problem, as only a fraction of the diffraction spots in a given image correspond to a single lattice. A further complication can arise from the presence of a subset of reflections (*e.g.* those lying on an axis of rotation that relates the twin domains) whose multiple distinct contributions from the different domains overlap in the diffraction pattern. Strategies for unit-cell determination and reflection integration have been developed and implemented in various X-ray data processing programs (Sparks, 1999; Sheldrick, 1997, 2002, 2004, 2008; Duisenberg, 1992; Herbst-Irmer & Sheldrick, 1998; Duisenberg *et al.*, 2003; Dix *et al.*, 2007). Those programs have been developed mainly in the context of small-molecule applications, but are often suitable for problems involving macromolecular crystals as well. We do not consider twinning by non-merohedry further in this chapter, but focus instead on a special category (Fig. 11.7.1.1) known as twinning by merohedry.

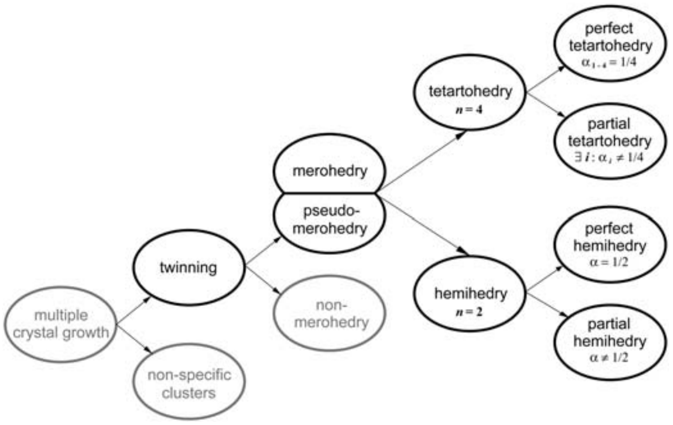

Figure 11.7.1.1
Hierarchy of multiple types of twinning. Merohedry is elevated over non-merohedry as it results in the exact superposition of diffraction patterns. Tetartohedry is ranked higher than hemihedry because it involves a larger number of domain orientations. Perfect merohedry is given higher rank than partial merohedry as it results in higher apparent symmetry than exists in the crystal. Darker print highlights the scope of the text. (Modified from Yeates & Fam, 1999.)

The synonymous term 'merohedral twinning' is also widely used in the macromolecular literature, although it has been noted that the latter usage introduces potential confusion in that the adjective 'merohedral', or '*mérohèdre*' (Friedel, 1926), is used in mathematical crystallography in a somewhat different context as a specific property of certain symmetries.

11.7.2. Twinning by merohedry – considerations of lattice symmetry

In twinning by merohedry, the lattices of the differently oriented domains are superimposable, although the operations that relate the domains are not operations of the space-group symmetry (Fig. 11.7.2.1). This is possible only in special symmetries, namely those where the rotational symmetry of the lattice exceeds the underlying rotational symmetry of the crystal space group; we consider only rotational operations here, in order to focus on situations relevant to biological macromolecules. Symmetries where this occurs are listed in Table 11.7.2.1; they include crystal point groups 4, 3, 312, 321, 6 and 23. Space group *P*4 provides a simple example. It requires a tetragonal lattice, and that lattice contains twofold axes of rotational symmetry (perpendicular to the fourfold axis) which are not utilized by the *P*4 symmetry of the crystal. Therefore, two separate crystal domains, each obeying *P*4 symmetry, can grow together within the same specimen in a way such that they are rotated with respect to each other by one of these twofold symmetry axes of the tetragonal lattice. The operation used to describe the rotation is referred to as the twin operation. Because the lattices of the two domains are indistinguishable, the separate domains give rise to diffraction patterns that exactly superimpose in reciprocal space. Therefore, multiple distinct reflections (*e.g.* one from each of the two twin domains) fall precisely on top of each other (Fig. 11.7.2.1). Because warning signs are usually not present during inspection of diffraction patterns, twinning by merohedry must be detected

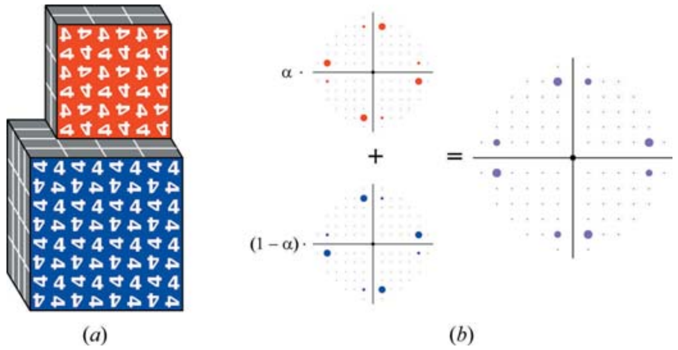

Figure 11.7.2.1
A cartoon depicting partial merohedral twinning in space group *P*4. (*a*) Two twin domains growing together, related by a twofold twin operation perpendicular to the fourfold symmetry axis. (*b*) The diffraction patterns of individual domains and their overlapping combination expected in a diffraction experiment. (Adapted from Yeates & Fam, 1999.)

Table 11.7.2.1
Symmetries in which twinning by merohedry can occur in biological macromolecules

Point group	Space groups	Apparent point group when $\alpha = 1/2$
4	$P4$ $P4_1$ $P4_2$ $P4_3$ $I4$ $I4_1$	422
3	$P3$ $P3_1$ $P3_2$ $R3$†	6 or 321 or 312‡
312	$P312$ $P3_112$ $P3_212$	622
321	$P321$ $P3_121$ $P3_221$	622
6	$P6$ $P6_1$ $P6_2$ $P6_3$ $P6_4$ $P6_5$	622
23	$P23$ $P2_13$ $I23$ $I2_13$ $F23$	432

† Excluding cases of reticular twinning, $R3$ can only be twinned towards $R32$. ‡ Point group 3 gives apparent symmetry 622 under perfect tetartohedral symmetry ($\alpha_{1\text{–}4} = 1/4$).

after data collection, and special steps must be taken during structure determination if unaffected crystals cannot be grown.

The case of space group $P4$ described above is an example of the simplest type of twinning by merohedry, namely where only two distinct domain orientations are possible. The case of two domain orientations ($n = 2$) is referred to as twinning by hemihedry. We focus mainly on hemihedry in this chapter but provide brief comments on higher-order cases, such as tetartohedry ($n = 4$), at the end. Another distinct category of twinning arises in crystals where the lattice very nearly obeys some higher rotational symmetry, not by virtue of a strict requirement, as in $P4$ and its tetragonal lattice, but because of a fortuitous geometry of the unit cell. These cases are referred to as twinning by pseudo-merohedry. A simple example is provided by a monoclinic crystal with the unique β angle very nearly equal to 90°. The lattice is nearly orthorhombic, in which it is possible to have two domain orientations related by a twofold rotation about one of the principal axes perpendicular to the crystallographic axis of twofold symmetry. Situations of twinning by pseudo-merohedry are relatively common (Rudolph *et al.*, 2004; Hamdane *et al.*, 2009). The method of treatment is similar to those of typical merohedry, but detection requires special attention since the phenomenon depends on specific unit-cell geometries. Modern software programs are able to detect cases where twinning by pseudo-merohedry is possible by identifying potentially higher metric symmetry within an apparently lower-symmetry unit cell (Adams *et al.*, 2002, 2004; Zwart *et al.*, 2005*b*). Yet another special case is reticular twinning, wherein only a subset of reflections are superimposed on others by the twinning operation while the remaining reflections are not overlapped (Herbst-Irmer & Sheldrick, 2002). The simplest case is space group $R3$, twinned about a twofold axis along **c** (for example); reflections for which $l = 3n$ overlap with other reflections in the same layer under the twin operation, while reflections in the other layers do not overlap. To date, reticular twinning is not well documented in macromolecular crystals and is not covered further here.

11.7.3. Considerations of length scale and effects in reciprocal space

Twinning is distinguished from other types of disorder by the length scale over which the disorder occurs. In cases of twinning, individual twin domains behave as ideal crystals whose sizes are presumed to be large compared with the coherence length of the X-ray beam. Therefore, the scattering from twinned specimens behaves as a sum of intensities from the separate twin domains, rather than as a sum of complex-valued structure factors; the X-ray scattering from one domain is presumed not to interfere with the scattering from the other domain(s). The organization of differently oriented domains in twinned crystal specimens has been studied in select cases (Efremov *et al.*, 2004; Ko *et al.*, 2001), but is generally not well understood for macromolecular crystals. Based on the behaviour of twinned crystals of small molecules, various types of physical arrangements are likely.

11.7.4. Extent of twinning: the twin fraction

The twin fraction describes the fractional volumes of the different domain orientations within a crystal specimen. In the case of twinning by hemihedry, just one twin fraction, α, needs to be specified. Its value is taken to be the minor component, meaning a value less than or equal to 1/2. The twin fraction dictates the relative weights with which two twin-related reflections contribute to each observed intensity. The basic system of equations is

$$\begin{aligned} I_{\rm obs}(\mathbf{h}_1) &= (1-\alpha)I(\mathbf{h}_1) + \alpha I(\mathbf{h}_2), \\ I_{\rm obs}(\mathbf{h}_2) &= \alpha I(\mathbf{h}_1) + (1-\alpha)I(\mathbf{h}_2), \end{aligned} \qquad (11.7.4.1)$$

where $\mathbf{h}_1$ and $\mathbf{h}_2$ are twin-related reflections, I represents the true crystallographic intensity of a reflection (*i.e.* the square of the structure-factor magnitude) and $I_{\rm obs}$ represents an observed intensity (Fig. 11.7.2.1).

The value of the twin fraction has a critical effect on how twinning manifests itself in practice. Two essentially distinct scenarios arise. First, if the twin fraction is significantly less than 1/2, a situation typically referred to as 'partial twinning' occurs, and partial higher symmetry may be evident during data processing and analysis. For example, if the true space group is $P4$ and the crystal specimen is partially twinned, one might find that the merging R value is lower than random when attempts are made to reduce the data under the higher tetragonal symmetry $P422$. Similarly, when the data set reduced in $P4$ is analysed using a self-rotation function, partial higher symmetry may be evident along what would be symmetry axes in $P422$. However, such symptoms can also be consistent with an alternative explanation, namely local or noncrystallographic symmetry (NCS) nearly coincident with potentially higher crystallographic symmetry ($P422$ in the present example). Discriminating partial twinning from pseudo-crystallographic NCS is therefore a key problem in analysing data in space groups that support twinning.

In the second scenario, the twin fraction α is very nearly 1/2, giving rise to a situation typically referred to as 'perfect twinning'. In that case, pairs of twin-related observations are necessarily equal. The recorded data set therefore obeys higher symmetry. For example, if a crystal in $P4$ is perfectly twinned by merohedry, the data set will obey 422 symmetry. The challenge in a case of perfect twinning is to recognize that the correct space-group symmetry is lower than that implied by the observed intensity data.

11.7.5. Indications of twinning

Unusual crystal morphology sometimes provides an early suggestion of twinning. In particular, concave crystals or crystals having 're-entrant' faces are suspect. However, most cases of twinning in macromolecules are not identified until structure determination is in progress. It is relatively rare, but in some cases twinning can be identified decisively when an impossibly dense molecular packing would be required to generate a crystal with symmetry as high as that implied by the observed data (Redinbo & Yeates, 1993). Sometimes, the possibility of twinning is raised during atomic refinement when, for unexplained reasons, the refinement R values cannot be brought down to acceptable limits. However, it should be emphasized that problematic refinement is never sufficient evidence by itself to conclude that a crystal is twinned; instead, a careful analysis of the observed data is required. Modern data-reduction programs now incorporate various statistical analyses for this purpose, making it relatively straightforward to identify the presence of twinning before proceeding further with structure determination.

Twinning has two related but distinct effects on intensity data. First, the observed intensities of twin-related reflections tend to be more similar to each other than expected for independent reflections; in the limit of perfect twinning they become equal. Second, the overall statistical distribution of intensities is affected, so that classic Wilson statistics are not obeyed. Therefore, two essentially different kinds of tests exist to analyse intensity statistics for the presence of twinning.

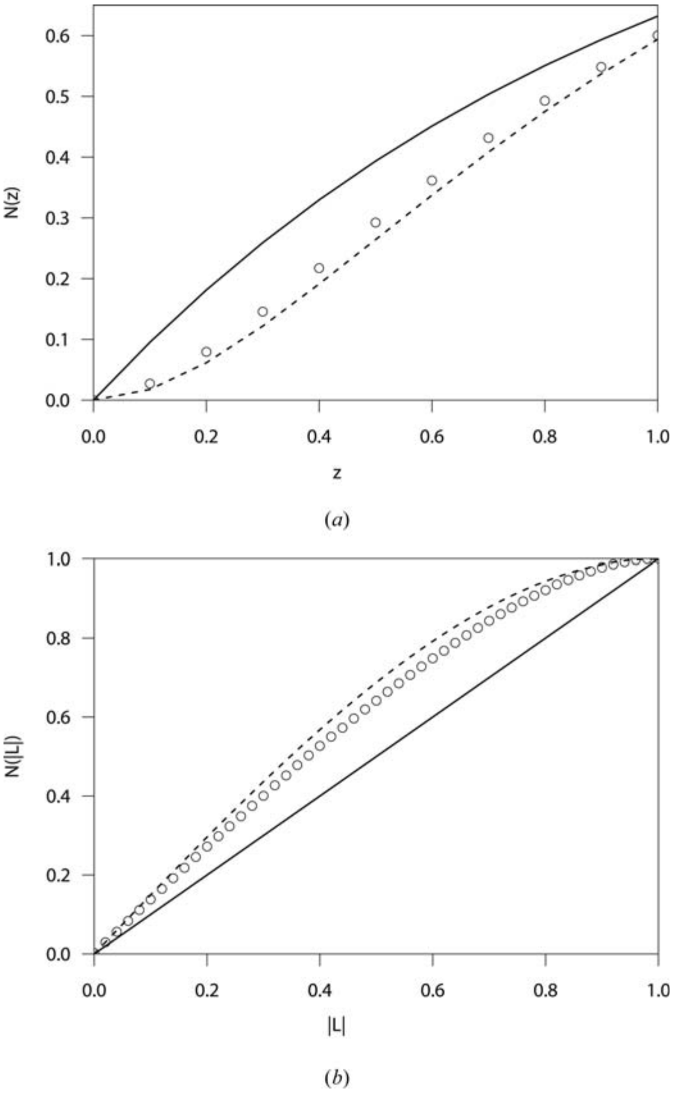

Figure 11.7.6.1
Detection of high or perfect twinning by analysing overall intensity statistics. (*a*) A traditional examination of cumulative intensity statistics. z is the normalized intensity and $N(z)$ is its cumulative distribution. Theoretical curves are shown for perfectly twinned (dashed line) and untwinned acentric data (solid line). The experimental curve (open circles) is for the protein Dicer [Protein Data Bank (PDB; Berman *et al.*, 2000) code 2qvw; MacRae & Doudna, 2007], which is essentially perfectly twinned. (*b*) A plot of the local intensity difference, L (see text). Theoretical curves for perfectly twinned (dashed line) and untwinned (solid line) data are shown. Data from a perfectly twinned crystal, VP5CT (Padilla & Yeates, 2003), are plotted with open circles. The crystal suffered from pseudo-centring, which did not interfere with the interpretation of twinning using local intensity statistics; reflection pairs were chosen to have indices differing by even numbers.

11.7.6. Twinning tests based on overall intensity statistics

Twinning causes a shift in the typical intensity distribution from an exponential to a sigmoidal shape (Fig. 11.7.6.1*a*). Various measures of the intensity distribution have been used to diagnose twinning. The Wilson ratio, $\langle F\rangle^2/\langle F^2\rangle$ (where the angle brackets denote the average), is 0.785 for ordinary acentric data and 0.885 for perfectly twinned data (Stanley, 1972; Wilson, 1949). Similarly, the value of $\langle|E^2-1|\rangle$ (where E^2 is defined as $F^2/\langle F^2\rangle$) is 0.736 for ordinary acentric data and 0.541 for perfectly twinned data (Bruker, 2000). The moments of the intensity distribution have simple, rational values. For example, the ratio $\langle I^2\rangle/\langle I\rangle^2$, sometimes referred to as the Stanley factor, is 2.0 for ordinary acentric data and 1.5 for perfectly twinned data (Stanley, 1972). For partial twinning, intermediate behaviour is observed and complex expressions for the resulting intensity distributions have been worked out (Rees, 1980). A key difficulty with these statistical tests is that they assume that the members of the set of reflections being evaluated all have the same expected value. If the diffraction is nearly isotropic, this condition can be satisfied relatively easily by normalizing the reflection intensities in thin resolution shells. In contrast, anisotropy presents a problem that must be corrected if these traditional tests are to be useful. If the anisotropy has a relatively simple form (*e.g.* if it follows an elliptical Gaussian function), then correction may be straightforward, but otherwise correction can remain problematic. Crystals in which distinct molecules in the asymmetric unit are related by translational shifts create similar problems: classes of strong and weak reflections are present in a single resolution shell. Cases of anisotropy and translational pseudo-symmetry both give intensity distributions that are shifted counter to the shift caused by twinning, and can therefore mask its presence.

One method for examining overall intensity statistics in a way that seeks to overcome the challenges described above has been described (Padilla & Yeates, 2003). Reflections near each other in reciprocal space are considered in pairs. The difference between the two intensities divided by their sum is taken as the quantity to be analysed,

$$L \equiv \frac{(I_{\mathrm{obs},A} - I_{\mathrm{obs},B})}{(I_{\mathrm{obs},A} + I_{\mathrm{obs},B})}, \qquad (11.7.6.1)$$

where L is the so-called local intensity difference, and $I_{\mathrm{obs},A}$ and $I_{\mathrm{obs},B}$ are the observed intensities of two reflections that are not related by any crystal symmetry or potential twin operation. Choosing the reflection pairs to be near in reciprocal space ensures that anisotropy effects will not affect their expected values differently. Countering translational pseudo-symmetry is a more difficult problem, but common cases of pseudo-centring or unit-cell doubling can be treated effectively by requiring that reflection pairs have the same parity (*i.e.* differ by an even value for all three indices). In principle, more complex types of pseudo-symmetry can be handled with additional care (Zwart *et al.*, 2005*a*).

For two ordinary (untwinned) acentric intensities following Wilson statistics, $|L|$ has a uniform probability distribution from 0 to 1. For perfectly twinned intensities, the distribution of L has a quadratic form. An observed data set can therefore be analysed and the cumulative distribution of $|L|$ compared with simple theoretical curves (Fig. 11.7.6.1*b*). Likewise, the expected values and moments of L are simple fractions for both untwinned and

Table 11.7.6.1
Twinning statistics for acentric intensity data from a crystal specimen with different numbers of twin domain orientations (n)

Values are given for crystals exhibiting no twinning (n = 1), perfect twinning by hemihedry (n = 2) and perfect twinning by tetartohedry (n = 4).

n	$\langle\lvert L\rvert\rangle$	$\langle L^2\rangle$	$\langle I^2\rangle/\langle I\rangle^2$
1	1/2	1/3	2
2	3/8	1/5	3/2
4	35/128	1/9	5/4

perfectly twinned cases (Table 11.7.6.1). Values for $\langle|L|\rangle$ are 1/2 and 3/8 for untwinned and perfectly twinned data, respectively.

When applying tests of overall intensity statistics, situations of partial twinning produce values intermediate between those expected for untwinned and perfectly twinned data. The twinning fraction can therefore be estimated by such tests. However, owing to systematic deviations of the types noted above, this is generally not the best way to estimate α. In particular, if α is small the presence of partial twinning can be missed. The strength of these tests is in identifying cases of high or perfect twinning. Consequently, an examination of overall intensity statistics is sometimes referred to as a test for perfect twinning. Such tests typically provide decisive support for a claim of high or perfect twinning.

11.7.7. Tests for partial twinning based on comparison of twin-related reflections

Once model-derived intensities become available during structure determination, the presence of partial twinning can be detected reliably and α can be estimated with high precision (see Chapter 18.12). However, at the outset of structure determination, identifying partial twinning unambiguously and estimating α are more challenging problems, and numerous methods have been developed. One method, referred to as a Britton plot and popularized by Fisher & Sweet (1980), is based on the behaviour of equation (11.7.4.1). Given a pair of twin-related observed intensities and a presumed value for α, the two underlying crystallographic intensities can be calculated by inverting the linear equations. If α is chosen to be higher than its correct value, this process leads to some of the crystallographic intensities having negative calculated values. The correct value of α can therefore be estimated by plotting the number of negative calculated intensities obtained as a function of α. For error-free data, the correct value for α is the highest value that gives no negative calculated intensities.

Other methods of estimating α evaluate the degree of similarity between twin-related intensities. Rees (1982) analysed the behaviour of the R value when calculated as a comparison over potentially twin-related intensities. If twinning is absent, the comparison is effectively between independent intensities, resulting in a random R value, which is 1 for acentric data. In the presence of twinning, the expected R value is $1 - 2\alpha$, providing an equation for extracting α from the R value over twin-related pairs. A related method takes twin-related reflections one pair at a time and evaluates the difference divided by their sum, to give a variable designated H (Yeates, 1988),

$$H \equiv \frac{[I_{\rm obs}(\mathbf{h}_1) - I_{\rm obs}(\mathbf{h}_2)]}{[I_{\rm obs}(\mathbf{h}_1) + I_{\rm obs}(\mathbf{h}_2)]}, \qquad (11.7.7.1)$$

where $I_{\rm obs}(\mathbf{h}_1)$ and $I_{\rm obs}(\mathbf{h}_2)$ are the observed intensities of two twin-related reflections, h_1 and h_2. The value of $|H|$ ranges from 0 to 1 for untwinned (acentric data) and has a uniform probability distribution. A plot of the cumulative distribution of $|H|$ is therefore linear. In the presence of twinning, $|H|$ takes on a restricted range from 0 to $1 - 2\alpha$ but remains uniformly distributed. A plot of $|H|$ therefore provides a relatively simple means of extracting α (Fig. 11.7.7.1). In addition, the expected value and moments for H relate simply to α. The value of $\langle|H|\rangle$ is $(1 - 2\alpha)/2$, while the value of $\langle H^2\rangle$ is $(1 - 2\alpha)^2/3$, providing equations for determining α from measured values of $\langle|H|\rangle$ or $\langle H^2\rangle$.

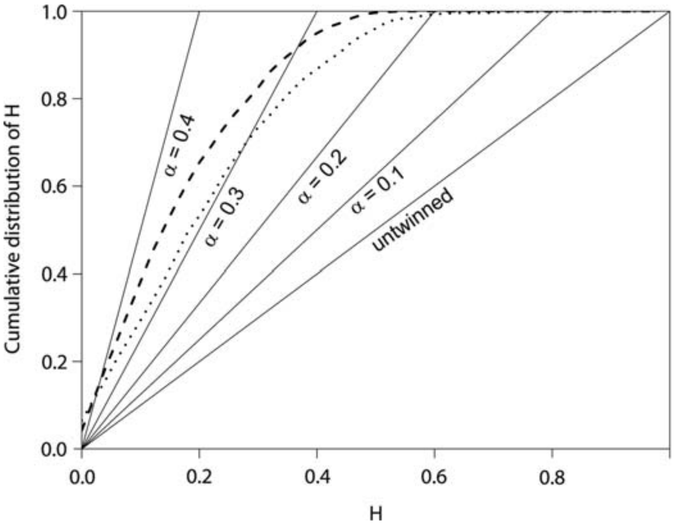

Figure 11.7.7.1
Estimation of the twin fraction α based on the variable H (see text). Two cases of twinning by hemihedry are shown, along with theoretical lines for different values of α. Results from diffraction data on dihaem *c*-type cytochrome DHC2 (PDB code 2czs; Heitmann & Einsle, 2008) are shown as a dashed curve. Results from *Escherichia coli* elongation factor Tu (PDB code 2fx3; Heffron *et al.*, 2006) are shown as a dotted curve. α is typically estimated from the central linear region of the observed curve.

Measurement errors complicate methods for estimating α. In a Britton plot, the ideally sharp transition that indicates the correct value for α becomes more gradual, leading to uncertainty. In methods that use measures of the average difference between twin-related reflections, ignoring the effects of errors causes α to be underestimated. Equations for incorporating the effects of errors have been discussed by Rees (1982), Fisher & Sweet (1980), Dumas *et al.* (1999) and Lunin *et al.* (2007). In general, measurement errors have a relatively small effect on estimates of α when the twin fraction is low, but have a much larger effect when the intensity measurement errors (on a fractional scale) are comparable with the deviation of α from 1/2.

Local or noncrystallographic symmetry (NCS) often presents challenging complications in relation to twinning. If a local symmetry operator nearly coincides with a crystallographic operator of some higher crystal symmetry, this gives rise to higher pseudo-crystallographic symmetry. Especially at lower resolution, reflections related by this operation will have similar intensities, and this can be mistaken for partial twinning. A further complication is that *bona fide* twinning often occurs in conjunction with NCS. One approach for resolving such complications is to analyse intensity statistics as a function of resolution. In cases where NCS is present but twinning is not, the similarity between potentially twin-related reflections typically decreases at higher resolution. In contrast, similarity between twin-related reflections persists out to the maximum resolution if twinning is present.

NCS can also occur in conjunction with perfect twinning. As before, resolution-dependent behaviour can be informative. Tests of overall intensity statistics (*i.e.* tests of perfect twinning) described earlier can appear relatively normal at low resolution where, owing to NCS, the true crystallographic intensities of twin-related reflections may be very similar to each other. If the true crystallographic intensities of twin-related reflections are nearly equal, twinning amounts to an averaging of values that are already nearly equal, which has little effect on intensity statistics. The effects of twinning on intensity statistics may be prominent only at higher resolution, where the true crystallographic intensities of twin-related reflections have diverged.

11.7.8. Higher forms of twinning

Types of twinning beyond hemihedry are possible. When four distinct twin domain orientations are involved, the situation is referred to as tetartohedry. For macromolecular crystals, twinning by tetartohedry is possible when the true symmetry of the crystal is primitive trigonal, *e.g.* $P3$. The crystal lattice has 622 rotational symmetry (order 12), which exceeds the rotational symmetry of $P3$ by a factor of four. Multiple cases have been reported (Rosendal *et al.*, 2004; Barends *et al.*, 2005; Gayathri *et al.*, 2007; Yu *et al.*, 2009). Twinning by pseudo-tetartohedry is possible in symmetries other than $P3$ if the unit-cell geometry obeys fortuitously high symmetry (Anand *et al.*, 2007). In twinning by tetartohedry, four crystallographic intensities contribute to each observed intensity. The effects on intensity statistics can therefore be even more pronounced compared with twinning by hemihedry. This is especially true when all four domain orientations are equally represented (*i.e.* the four underlying twin fractions are all 1/4), a situation referred to as perfect tetartohedry. In that case, the ratio $\langle I^2\rangle/\langle I\rangle^2$ is expected to be 5/4 (Stanley, 1972) and the value of $\langle|L|\rangle$ is expected to be $35/128 \simeq 0.273$ (Table 11.7.6.1). Less extreme values are expected for partial tetartohedry.

Twinning by partial tetartohedry can manifest itself as a crystal that appears to be partially twinned according to multiple distinct twin laws. However, cases of tetartohedry cannot be described properly in terms of a set of estimated hemihedral twin fractions (*e.g.* one for each twin law). Whereas the twin fraction α (and its complement $1 - \alpha$) can be estimated in the case of hemihedry by comparing pairs of twin-related reflections, the four twin fractions (which sum to unity) in the case of tetartohedry must be estimated by performing statistical tests on quadruplets of twin-related reflections. Equations and methods for that purpose are provided by Yeates & Yu (2008).

11.7.9. Other kinds of disorder

Macromolecular crystals can suffer from disorders other than twinning. These are not covered in depth here, but similarities and differences between twinning and a class of problems known as order–disorder (OD) phenomena are worth noting. In OD phenomena, alternative molecular positions or orientations occur over a short range within a crystal, from one layer to another for instance, in a stochastic fashion (Dornberger-Schiff, 1956; Dornberger-Schiff & Grell-Niemann, 1961). When the stochastic variation between layers or between rows is a translation, this is referred to as lattice-translocation disorder (LTD). Several cases of OD have been described and most have been of the LTD type (Wang, Kamtekar *et al.*, 2005; Wang, Rho *et al.*, 2005; Hwang *et al.*, 2006; Tanaka *et al.*, 2008; Zhu *et al.*, 2008; Hare *et al.*, 2009; Tsai *et al.*, 2009), while cases involving alternately oriented layers are known, but less common (Pletnev *et al.*, 2009). Similar to twinning, OD phenomena can complicate structure determination and prevent proper atomic refinement. However, the symptoms and treatments differ from those for twinning. A distinguishing feature is the length scale of the disorder. In OD cases, differently oriented or translated molecules are nearby in the crystal and therefore scatter coherently. The intensity statistics are therefore not shifted in the same way as for twinning. Furthermore, the interference between alternatively positioned molecules in the case of LTD is typically evident by major non-origin peaks in a native Patterson map, often appearing to be impossibly close to the origin. In addition, LTD diffraction patterns often show prominent streaking in all or a subset of reflections. Another situation that often arises in OD cases is the appearance of sterically impossible (*e.g.* interpenetrating) electron density during model building. This can arise when the model accounts for some of the molecules in the unit cell, but others (typically in alternative, mutually exclusive, orientations or positions) have not been accounted for. In contrast, unexplained or interpenetrating electron density is generally not observed in twinning, owing to the absence of coherent scattering between differently oriented twin domains.

11.7.10. Summary

In situations where symmetry permits it, twinning is fairly common in macromolecular crystals. If twinning is present but goes undetected, problems arise in later stages of structure determination. Partial and perfect twinning lead to distinct scenarios, but statistical tests make it possible to uncover both kinds of problem. Local or noncrystallographic symmetry, which very often occurs together with twinning, can complicate the interpretation. Resolution-dependent analysis can help to clarify these cases. Additional challenges occur with more complex types of twinning, such as tetartohedry, which is being recognized with increasing frequency.

The authors thank Michael Sawaya, Regine Herbst-Irmer and George Sheldrick for helpful comments on the manuscript.

PART 12. ISOMORPHOUS REPLACEMENT

Chapter 12.1. The preparation of heavy-atom derivatives of protein crystals for use in multiple isomorphous replacement and anomalous scattering

D. Carvin, S. A. Islam, M. J. E. Sternberg and T. L. Blundell

12.1.1. Introduction

The traditional method of multiple isomorphous replacement (MIR) was introduced by Perutz and co-workers in 1954 (Green *et al.*, 1954) and is often enhanced by anomalous scattering (MIRAS) [see Blundell & Johnson (1976) for a review]. The method remains popular for solution of the phase problem in the absence of the structure of a close homologue, although the use of multiple anomalous dispersion is likely to increase in the coming years (Hendrickson, 1985).

Protein crystals comprise an open lattice of protein molecules with solvent occupying the channels and spaces which normally comprise between 30 and 80% of the crystal volume. The preparation of a useful derivative requires the binding of a heavy atom to a specific position, usually on the protein surface, for example by the displacement of a lighter solvent molecule or an ion, without distorting the protein or crystal lattice.

Ideally, rational selection of suitable heavy-atom reagents requires a comprehensive knowledge and understanding of the crystalline structure of the protein. Normally, this information is unavailable since it is the objective of the crystal structure analysis! Nevertheless, the sequence and mechanism of action may suggest which heavy-atom reagents might be employed. There are reports in the literature of many attempts to make synthetic analogues of specific amino acids, by substituting selenium for sulfur residues in a chemically synthesized polypeptide or by removing an amino-terminal residue by the Edman technique and replacing it with an amino acid modified by a heavy atom [see Blundell & Johnson (1976) for a review]. Alternatively, analogues of the substrate of an enzyme or carrier protein can sometimes be modified with a heavy atom; however, this will disturb the active site, which is usually the region of greatest interest to the structural biologist. Such methods have not proved very useful and will not be described further here. Most proteins studied now are recombinant; site-directed mutagenesis can replace methionines in the sequence, which occur on average once every fifty residues, by selenomethionines (Hendrickson *et al.*, 1990) or more recently by telluromethionines (Budisa *et al.*, 1997). Such approaches have revolutionized macromolecular crystallography through the use of anomalous-dispersion techniques, but have yet to provide a very efficient method of introducing atoms heavier than selenium into proteins.

Thus, the vast majority of successful heavy-atom derivatives employed in crystallographic analyses are obtained on a trial-and-error basis. In earlier studies, the protein was often covalently modified, purified and characterized before crystallization. There are some useful covalent modifications, for example, the reaction of mercury with the sulfhydryl groups of cysteinyl side chains and the iodination of tyrosyl side chains. The replacement of a metal-ion cofactor, such as calcium or zinc, can also give a useful derivative. However, pre-reaction of the protein often gives rise to conformational changes in the protein, and crystallization frequently occurs in a different or non-isomorphous form.

Most heavy-atom derivatives are produced by direct soaking of the crystals in a solution of the heavy-atom compound. With this approach, heavy-atom substitution patterns tend to be complex, with sites frequently only partially occupied. The specificity is often determined by entropic factors. Thus, sites between molecules in the crystal lattice, or between several different side chains brought together by the tertiary structure, may bind the metal ion, even if the side chains individually do not have strong affinity for the metal. Chelation is entropically driven, and bonds may form with unusual protein ligands, a major factor causing lack of specificity.

Blake (1968) reviewed the data available for heavy-atom binding to proteins and suggested some generalizations. These were extended in a comprehensive review of protein heavy-atom derivatives (Blundell & Johnson, 1976; Blundell & Jenkins, 1977) which analysed the dependence of reactivity on protein side chain identity, nature of the reagent, pH, concentration, buffer *etc*. Over the past two decades, there have been discussions of the binding of some particular metal ions, but there have been no comprehensive analyses. Furthermore, protein–heavy-atom interactions have not often been fully described in publications of protein crystallographic analyses, and, in any case, the information has not been available in a format that could be used for systematic computer-based analysis.

We have now collected, either from the literature or directly from protein crystallographers, information on the preparation and characterization of heavy-atom derivatives of protein crystals. We have defined heavy atoms as those with an atomic weight greater than that of rubidium. We have assembled the information in the form of a data bank (Carvin *et al.*, 1991; Islam *et al.*, 1998) in which the coordinate data for the heavy-atom positions are compatible with the crystallographic data in the Protein Data Bank (Bernstein *et al.*, 1977). The data bank contains a wealth of information and provides the basis for further, more detailed analyses of heavy-atom binding to proteins. The information can be directly accessed and should be useful to protein crystallographers seeking to improve their success in preparing heavy-atom derivatives for isomorphous replacement and anomalous dispersion.

In this chapter we provide an introduction to the data bank and we review strategies that can be adopted in the preparation of heavy-atom derivatives of protein crystals for use in MIRAS.

12.1.2. Heavy-atom data bank

The heavy-atom data bank (HAD) is a computer-based archival file system that contains experimental and derived information from successful multiple isomorphous replacement analyses in the determination of protein crystal structures. HAD is available

Copyright © 2012 International Union of Crystallography

at http://www.sbg.bio.ic.ac.uk/had/. The data bank makes available information which is otherwise only accessible in a widely distributed and fragmented form throughout the scientific literature or even unpublished in laboratory files.

The data bank contains information on heavy-atom derivatives for 969 protein crystals, 600 of which are deposited in the Protein Data Bank (PDB). A further 200 proteins are being processed at present. It contains information on the physical and chemical characteristics of each chemical compound that has proved successful in past protein crystallographic analyses: this includes the IUPAC name, trivial name, molecular formula, oxidation state, solution chemistry and stereochemistry. Experimental details of the preparation of the heavy-atom derivatives include the source of the protein, concentration of the heavy-atom solution, pH values, soak times and details of the buffer compositions used in the experiments; 3164 different experimental conditions are recorded. The atomic coordinates are given in the same format as the PDB coordinates for the 5500 binding sites of the heavy atoms. A statistical analysis is included for each of the 456 heavy-atom reagents; this includes range of pH values and a summary of the amino acids involved at the binding sites. For metalloproteins, it gives details of the type, number, geometry of coordination and function of the native metal(s) present. This is followed by a description of the procedure for native-metal substitution and details of the coordination of the substituted heavy atom. It also includes an extensive bibliography and references to other relevant web sites.

12.1.3. Properties of heavy-atom compounds and their complexes

Potential ligands for heavy-atom reagents may be derived from the functional group(s) of reactive amino-acid side chains, from the buffer and from salting out/in agents. We must first consider factors that will influence the formation of such complexes in the environment of a protein crystal.

12.1.3.1. Stability

Ligands may be classified as either hard or soft. Hard ligands tend to be electronegative and interact electrostatically, with little delocalization of electron density. Water molecules, glutamates, aspartates, terminal carboxylates, and hydroxyl groups of serine and threonine from the protein, as well as acetate and citrate ions from the buffer, fall into this category. Conversely, soft ligands are polarizable and tend to form covalent bonds. Typical examples include the anions Cl^-, Br^-, I^-, S^{2-}, CN^-, imidazole, methionine, cysteine, cystine and histidine from the protein. Ligands can be listed in series of increasing hardness:

$$I^- > Br^- > Cl^- \gg F^- \gg H_2O,$$
$$RS^- > R_2S \gg NH_3 > H_2O,$$
$$CN^- > RNH_2 > Cl^- > CO_2^- > \text{—OH of alcohol.}$$

The metal components of the reagents may be classified as hard (class A) or soft (class B) in a similar way. Class A metals include the alkali metals, the alkaline earth metals, the lanthanide and actinide series, and the first-row transition metals from group III to group VA. Many of these metal ions have an inert-gas structure in which the electrons are held very strongly and tend to be non-polarizable. Metal ions in this class tend to interact with hard ligands, including the acetate, citrate and phosphate buffer components of mother liquor systems. On the other hand, class B metals have a preference for binding soft ligands. This group includes most members of the second and third row of the transition series (*e.g.* Ag, Cd, Pt, Au, Hg), which form cations such as $Pt(NH_3)_4^{2+}$ or anions such as $Au(CN)_2^-$, $PtCl_4^{2-}$ and HgI_4^{2-}. The easily polarizable *d* electrons allow formation of covalent bonds with methionine, cysteine and imidazole, so displacing the ligands of the complexes. In the middle and towards the end of the first transition-metal series, the ions have properties intermediate between class A and B metals. Class B character increases in the series:

$$Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} < Zn^{2+}.$$

Thus, zinc binds to the polarizable sulfur of cysteine and imidazole of histidine as well as to carboxylates and water molecules. Tl^+ and Pb^{2+}, which each have an inert pair of electrons in their outer shell, are stable cations and prefer carboxylate rather than sulfur ligands or imidazole.

12.1.3.2. Lability

The rates at which ligands enter and leave a metal complex are important in the formation of heavy-atom derivatives, especially the covalent complexes of mercury, gold and platinum. The rate-determining step in unimolecular S_{N1} reactions is the expulsion of the leaving ligand from the metal complexes, which often proceeds relatively slowly. The intermediate complex, once formed, reacts with the entering ligand almost instantly. For S_{N1} reactions, the rate is directly proportional to the intermediate complex concentration but independent of the ligand concentration. The bimolecular S_{N2} mechanism involves attack by the ligand on the metal complex to form an intermediate complex, which then ejects the displaced ligand. The rate of reaction is proportional to the concentration of the initial species and the concentration of the nucleophile. S_{N2} reaction rates are dependent on the nature of the leaving group and the attacking nucleophile in the following ways:

$$\text{Relative rates of attack: } RS^- > I^- > Br^- > NH_3 > Cl^- > RO^-;$$
$$\text{Rate of leaving group: } H_2O > Cl^- > NO_2^- > CN^-.$$

Sulfur ligands are good nucleophiles but poor leaving groups. They form thermodynamically stable complexes. The rate of leaving is influenced by the *trans* effect in square-planar complexes of Au(III) and Pt(II). Thus groups in square-planar complexes *trans* to NH_3 are difficult to displace. This has implications for attempts to make derivatives of proteins in ammonium sulfate, where ligands may be replaced by NH_3.

Rates of reaction depend not only upon which ligands are present in a heavy-atom complex but also on the character of the metal. For example, $PtCl_4^{2-}$, $AuCl_4^-$ and $PdCl_4^-$ have similar square-planar geometries (Petsko *et al.*, 1978), but the rates of substitution vary:

$$PdCl_4^- > PtCl_4^{2-} > AuCl_4^-.$$

Thus, if the reaction between the protein and a palladium or platinum complex is proceeding too fast, a gold derivative might be investigated.

12.1.3.3. Oxidation state of metal ions in protein crystals

In the environment of a living cell, the following oxidation states tend to be stable:

Os(II), Ru(II), Ir(III), Rh(III), Pt(II), Pd(II), Au(I).

12.1.3.4. Effect of pH

Although the pK_a of an individual amino acid in solution is generally defined within narrow limits, environmental and steric

Table 12.1.3.1

Useful pH ranges of some heavy-atom reagents derived from the heavy-atom data bank

No. of entries	Minimum	Average	Maximum	Compound
159	3.0	6.7	9.1	Potassium tetrachloroplatinum(II)
63	4.2	6.6	9.0	Potassium dicyanoaurate(I)
53	4.2	6.9	9.5	Mercury(II) chloride
59	2.8	6.7	9.0	Mercury(II) acetate
52	4.7	6.7	9.3	4-(Chloromercurio)benezenesulfonic acid
57	2.0	6.5	9.3	Potassium tetraiodomercurate(II)
36	5.4	6.7	8.5	Ethylmercurythiosalicylate (EMTS)
46	4.0	6.0	8.0	Potassium pentafluorooxyuranate(VI)
2	8.2	8.4	8.5	Barium(II) chloride
22	4.0	6.2	8.1	Lead(II) acetate
13	4.5	6.6	7.5	Lead(II) nitrate
1	6.5	6.5	6.5	Strontium(II) acetate
3	6.3	6.8	7.5	Thallium(I) acetate
2	5.9	6.6	7.2	Thallium(III) chloride
5	5.0	5.8	6.8	Gadolinium(III) chloride
9	4.9	6.7	7.5	Samarium(III) nitrate
7	4.9	6.6	8.7	Neodymium(III) chloride
64	4.1	6.3	8.6	Uranium(VI) oxyacetate

factors give rise to a wide range of values in proteins. Thus, the hydrogen-ion concentration influences the thermodynamic and kinetic stability of potential complexes. Protons compete with heavy-atom ions for the available binding site(s) on the protein. For example, below pH 3.5, cations bind less well to aspartic and glutamic acids due to the protonation of the carboxylate groups.

The nucleophilicity of histidine increases when it loses its proton, and thus its positive charge changes from around pH 6.0 to 7.0. Similarly, the nucleophilicity of cysteine increases dramatically when the thiolate ion is formed at pH $\sim$ 8.0. The thiolate ion is a stronger nucleophile than the thioether group of methionine, but when it becomes protonated it is considerably less effective. The nucleophilicity of the attacking groups varies in the order

$$RS^- > R_2S > RSH.$$

Thus the number and occupancy of sites can be manipulated by varying the pH, often after cross-linking the crystals to stabilize them.

Extremes in pH can give rise to considerable difficulties in establishing suitable derivatives, as hydrogen and hydroxyl ions compete with the metal ion/complex for the protein and with the protein for the metal ion/complex. At extremely high pH values metals in solution tend to form insoluble hydroxides. The ranges of pH values that are useful for metal ions are given in Table 12.1.3.1.

Varying the reactivity of amino-acid side chains by manipulation of the pH can enable the same heavy-atom ion/complex to bind at different sites, thus producing more than one derivative useful for phase determination.

12.1.3.5. Effect of precipitants and buffers on heavy-atom binding

Components present in the heavy-atom solution can have a profound effect on protein–heavy-atom interactions. The salting in/out agent (precipitant) and buffer are the principal sources of alternative ligands for the heavy-atom reagents, while protons compete with the heavy-atom ion/complex for the reactive amino-acid side chains.

Ammonium sulfate is the most successful precipitant in protein crystallization experiments (Gilliland *et al.*, 1994). However, its continued presence in the mother liquor can cause problems by interfering with protein–heavy-atom interactions. At high hydrogen-ion concentrations, the NH_3 group is protonated (*i.e.* NH_4^+), but as the pH rises the proton is lost, typically around pH 6.0–7.0, enabling the group to compete with the protein for the heavy-atom reagent by an S_{N2} reaction.

The nucleophilic strength of potential ligands follows the order

$$NH_3 > Cl^- > H_2O.$$

The anionic complex $PtCl_4^{2-}$ is present in excess ammonia at pH > 7.0 and it will react:

$$PtCl_4^{2-} \rightarrow cis\text{-}PtCl_2(NH_3)_2 \rightarrow Pt(NH_3)_4^{2+}.$$

The resultant cationic complex is less susceptible to reaction due to the *trans* effect of NH_3. Pd, Au, Ag and Hg complexes react in a similar way. Decreasing the pH of the solution reduces the amount of free ammonia available through protonation (Sigler & Blow, 1965). Such a technique may give rise to other problems (*e.g.* cracked crystal, decreased nucleophilicity of the protein ligands).

Changing the precipitant to sodium/potassium phosphate or magnesium sulfate may alleviate the situation, but it may also present other problems. For instance, PO_4^{3-} displaces Cl^- from $PtCl_4^{2-}$, thus increasing the negative charge. Both PO_4^{3-} and SO_4^{2-} form insoluble complexes with class A metals (*e.g.* lanthanide and uranyl cations) (Petsko *et al.*, 1978). Both acetate and citrate form complexes with class A metals, but citrate, a chelating ion, binds more strongly. Tris buffer is probably preferable; it binds many cations, but the complexes formed tend to be relatively unstable.

12.1.3.6. Solubility of heavy-atom compounds

The solubility of a heavy-atom compound will depend upon the precipitant, buffer and pH. Typically, the component present in the highest concentration is the precipitant, either as salts (*e.g.* ammonium sulfate) or as an organic-based reagent (*e.g.* ethanol, MPD, PEG). Heavy-atom compounds that are essentially covalent and organic in character will be more soluble in ethanol, MPD, PEGs and other organic precipitants.

Although the solubility of tetrakis(acetoxymercurio)methane (TAMM) is higher than most multiple-heavy-atom compounds in aqueous solutions, the presence of glycylglycine or charged mercaptans, such as cysteamine or penicillamine, can increase solubility further (Lipka *et al.*, 1976). The ratio of TAMM to solubilization agent (*e.g.* glycylglycine) is typically 1:10. Even so, the final solubility of TAMM depends on the concentration of competing anions (*e.g.* chloride) (O'Halloran *et al.*, 1987).

Many organometallic compounds are relatively insoluble in aqueous solutions, but their solubility may be increased by predissolving in an aprotic solvent such as acetonitrile.

Iodine and several inorganic iodide salts are insoluble in aqueous solutions. This can be rectified by dissolving the heavy-atom compounds in an aqueous solution of KI.

12.1.3.7. Effect of concentration, time of soak and temperature on heavy-atom binding

Most heavy-atom derivatives are prepared by diffusing or dialysing the compound into the crystals. Concentrations have typically ranged from 0.1–100.0 m*M*. Occasionally, concentrations as low as 0.001 m*M* have been employed to maintain crystal integrity. Low concentrations favour sites where the interactions between the heavy atom and the protein ligands are strongest. Decreasing the number of non-specific interactions minimizes the amount of heavy-atom reagent in the lattice. The latter absorbs X-rays without contributing to the diffraction pattern except at low angles. Increasing the concentration may give rise to other binding site(s). Usually, the higher the concentration employed, the shorter the soak time required for equivalent substitution. Short soak times at high concentrations tend to denature the crystals more often than long soaks at low concentrations. At very high concentrations (*i.e.* > 100 m*M*), the heavy-atom compound perturbs the protein crystal–mother liquor equilibrium by withdrawing water molecules from the hydration shell around the periphery of the crystal. Disorder of the crystals can sometimes be avoided by the application of a cross-linking reagent (*e.g.* glutaraldehyde). The optimal concentration is the lowest concentration that consistently reproduces intensity differences in the diffraction pattern of 15–25% without cracking and disordering the crystals.

Length of soak may be important. The heavy-atom data bank shows that, typically, soak times range from one day to one week. Useful derivatives have been prepared with a soak time of an hour to over a year. If no binding is apparent after several days, extending the soak time to over a week may produce some binding, but this is rare. Soaks of 24 hours for simple inorganic salts and up to one week for other types of heavy-atom compounds will normally suffice when screening for binding. The concentration of the heavy-metal compound that can be achieved will depend on its solubility in the crystal stabilization solution. Normally, the longer the soak, the greater the occupancy. Exceptions can arise due to undesirable chemical reactions between components present in the derivatization solution.

For covalent-bond formation, the length of soak and the concentration can be short (*e.g.* 1 h, 0.01 m*M*). This is especially true for mercury derivatives of proteins that have reactive sulfhydryls (Ringe *et al.*, 1983).

Variations in the temperature can also alter the rate of reaction. The UO_2 acetate derivative of rhombohedral insulin binds twenty times more slowly at 4 °C than at ambient temperature (Blundell, 1968). A lower temperature allows greater control over the rate of substitution. Conversely, heavy-atom derivatives that do not appear to bind may do so upon elevation of the temperature.

12.1.4. Amino acids as ligands

The reactivity of the heavy-atom reagent will also depend on the state of the amino-acid residues in the protein.

The thiolate anion of *cysteine*, a potent nucleophile, reacts almost irreversibly with mercuric complexes or organomercurials. It also acts as a fast-entering attacking group in S_{N2} ligand substitution reactions with other class B metals (*e.g.* Ag, Ir, Rh, Pt, Pd, Au), forming stable complexes. Below pH 6, the thiolate anion becomes protonated. As covalent reactions are less sensitive to hydrogen-ion concentration than ligand substitution reactions, cysteines still bind rapidly with mercurials, but there is negligible reaction with other class B metals (Petsko *et al.*, 1978).

Cystines are very weakly reactive in ligand substitution reactions. However, $PtCl_4^{2-}$ binds to disulfides in some proteins with displacement of a chloride ion (Lipscomb *et al.*, 1970; Sigler *et al.*, 1968). Mercurials rarely insert spontaneously into disulfide linkages. However, substitution of mercury can be achieved either by the prior application of a reducing agent such as dithiothreitol (Ely *et al.*, 1973; Sperling *et al.*, 1969), or by direct application of reducing mercurous ions (Sperling & Steinberg, 1974).

The non-ionizable thioether group of *methionine* is unreactive towards mercurials, but the lone pair of electrons on sulfur allows nucleophilic S_{N2} ligand substitution. Methionine will displace Cl, I, Br and NO_2 ligands from platinum complexes to form a stable bond. The reaction of methionine with platinum compounds is not pH sensitive within the normal range. The residue may become unreactive through oxidation, first to the sulfoxide and then to the sulfone; only the sulfoxide can be reduced readily by thiols or other reducing agents.

Below pH 6, *histidine* exists mainly as an imidazolium cation. Although this is not reactive as a nucleophile, it can interact electrostatically with anionic complexes. At pH 7 and above, the unprotonated imidazole is a good nucleophile, being able to displace Cl, Br, I and NO_2 ligands from platinum, silver, mercury and gold complexes. Electrophilic substitution of iodine in the imidazole ring is feasible, but the conditions are severe and it has not proved very useful in preparing derivatives.

At pH < 8.5, the ε-amino group of *lysine* is protonated, allowing it to form weak electrostatic interactions with anionic heavy-atom complexes, but not to participate in S_{N2} substitution reactions. Above pH 9, the free amino group can displace Cl but not Br, I or NO_2 ligands from platinum and gold complexes. The pK_a of the guanidinium group of *arginine* is very high (>12 in proteins), so it interacts electrostatically as a cation with heavy-atom anionic complexes.

The indole ring of *tryptophan* is relatively inert to electrophilic substitution by iodine, but the ring nitrogen can be mercurated (Tsernoglou & Petsko, 1976). The reaction is not pH dependent, but there should be no competing nucleophiles in the mother liquor. Tryptophan does not usually participate as a ligand in substitution of heavy-atom complexes.

The phenolate oxygen anion of *tyrosine* is a good nucleophile and has the potential to bind a substantial number of heavy-atom complexes *via* S_{N2} ligand substitution reactions. However, it has a very high pK_a value of 10.5. Below pH 10, the protonated oxygen predominates, making electrophilic aromatic substitution by iodine the principal reaction.

Aspartic and glutamic acids have side-chain pK_a values in the range 3 to 4. At low pH, they will be protonated and unreactive. Above pH 5, the side chains will be anionic, making them good

Table 12.1.5.1
The 23 most commonly used heavy-atom reagents

The first column gives the number of times the reagent has been used in the analyses included in the heavy-atom data bank.

No.	Compound
287	Potassium tetrachloroplatinum(II)
111	Potassium dicyanoaurate(I)
103	Uranyl acetate
101	Mercury(II) acetate
98	Mercury(II) chloride
85	Ethylmercurythiosalicylate (EMTS)
82	Potassium tetraiodomercurate(II)
81	*para*-Chloromercuriobenzenesulfonate (PCMBS)
75	Trimethyllead(IV) acetate
73	Potassium pentafluorooxyuranate(VI)
73	Phosphatotris(ethylmercury)
61	Potassium tetranitritoplatinum(II)
60	Uranyl nitrate
58	Potassium tetracyanoplatinum(II)
57	Dichlorodiammineplatinum(II)
51	Potassium hexachloroplatinum(IV)
51	Methylmercury chloride
44	Potassium tetrachloroaurate(III)
42	*para*-Chloromercurybenzoate (PCMB)
39	Lead(II) acetate

ligands for class A cations such as uranyl and rare earths. *Glutamine and asparagine* take part in metal coordination but rarely bind strongly enough to metal ligands on their own.

Hydroxyl groups of *serines and threonines* are fully protonated at normal pH values and are consequently not reactive nucleophiles. Abnormally reactive serines, usually at the active site as in serine proteases and β-lactamases, can react with heavy-atom reagents to give useful derivatives.

12.1.5. Protein chemistry of heavy-atom reagents

The heavy-atom data bank (Islam *et al.*, 1998) can be used to analyse the most commonly used heavy-atom reagents: these are given in Table 12.1.5.1. This shows that platinum, gold, mercury and uranyl have provided the most useful reagents.

The heavy-atom data bank can be used as a source of information about the reactivity of proteins to different heavy-atom reagents. This provides the basis for the following analysis.

12.1.5.1. Hard cations

Uranyl-ion complexes have proved the most popular A-group metal reagents for preparing heavy-atom derivatives of protein crystals (see Table 12.1.5.1). UO_2^{2+} is a linear, covalent group based on U(VI), the most stable oxidation state of uranium. Table 12.1.5.2 lists the most commonly used uranyl derivatives. Uranyl compounds may show 2 + 4, 2 + 5, or 2 + 6 coordination, with ligands lying in or near a plane normal to the $O{=}U{=}O^{2+}$ axis. These equatorial ligands may be neutral (*e.g.* H_2O) or anionic (*e.g.* NO_3^-, CH_3COO^-, oxalate^{2-}, F^-, Cl^1 or O_2^-); the nitrate and acetate are bidentate ligands. An example is given in Fig. 12.1.5.1. Anionic complexes, such as $UO_2F_5^{3-}$, have been found near negatively charged amino-acid residues (*e.g.* Glu and Asp), suggesting that the equatorial ligands have been displaced. At low pH, uranyl groups have been located near the hydroxyl groups of threonine and serine residues.

The fifteen lanthanides have similar chemical properties and are generally used as nitrates, acetates or chlorides (Blundell & Johnson, 1976; Carvin, 1986). The lanthanide contraction, a steady decrease in size with increasing atomic number, allows selection of an ion with a radius that will give high occupancy and isomorphism. Gadolinium and samarium salts have the added advantage that the number of anomalous electrons is high.

Table 12.1.5.2
The five most popular uranium derivatives

The first column gives the number of times the reagent has been used in the analyses included in the heavy-atom data bank.

No.	Compound
103	Uranyl acetate
73	Potassium pentafluorodioxyuranate(VI)
60	Uranyl nitrate
8	Uranium(VI) oxysulfate
4	Sodium triacetatedioxyuranate(VI)

Lanthanide ions have greater selectivity than the uranyl ion, which often forms clusters on the protein surface. Uranyl complexes and lanthanide ions are not very soluble above pH 7 and pH 9, respectively, due to the formation of hydroxides. Phosphate buffers should be avoided since they will compete for the heavy atom, often giving insoluble phosphates. In the presence of citrate, samarium is chelated and, since the citrate is difficult to replace, reaction may be inhibited. However, exchanging the buffer for Tris or acetate may enable a useful derivative to be obtained.

12.1.5.2. Thallium and lead ions

Thallium and lead can provide useful derivatives, especially in their lower oxidation states, Tl(I) and Pb(II), when they resemble class A metals. Owing to the non-group valence and presence of an inert pair of electrons, the ionic radii of Tl^+ (1.44 Å) and Pb^{2+} (1.21 Å) are greater than most class A metals. Thallous and plumbous cations prefer carboxylate rather than imidazole or sulfur ligands, although Pb^{2+} occasionally manifests its intermediate character by interacting with imidazole groups. Thallic (Tl^{3+}) and plumbic (Pb^{4+}) ions are similar to class B metals, showing preferential binding to soft ligands, but they are easily reduced in protein solutions.

12.1.5.3. B-metal reagents

The most useful members of the B-metal group, platinum, gold and mercury, give rise to an extensive range of heavy-atom

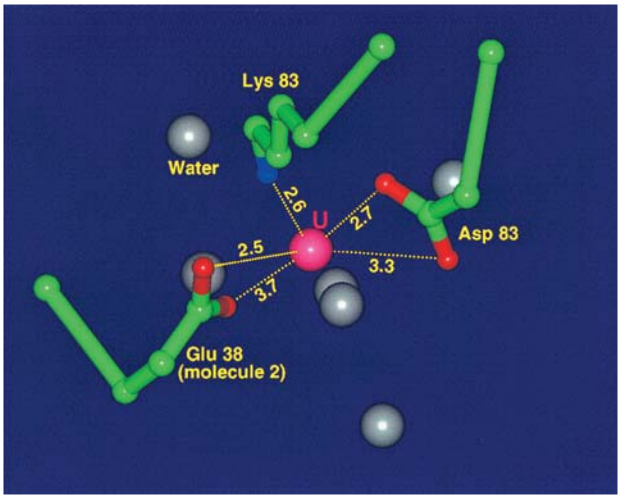

Figure 12.1.5.1

Table 12.1.5.3
The five most popular mercury derivatives

The first column gives the number of times the reagent has been used in the analyses included in the heavy-atom data bank.

No.	Compound
101	Mercury(II) acetate
98	Mercury(II) chloride
85	Ethylmercurythiosalicylate (EMTS)
82	Potassium tetraiodomercurate(II)
81	*para*-Chloromercuriobenzenesulfonate (PCMBS)

compounds which form covalent, electrostatic and van der Waals complexes with proteins. Some compounds can bind to the protein molecule in different ways; for example, $PtCl_4^{2-}$ can bind either covalently to the thioether group of methionine or electrostatically with positively charged residues.

Mercury compounds have proved very successful for preparing heavy-atom derivatives of protein crystals (Table 12.1.5.1), mainly due to the ease of formation of covalent bonds with cysteine residues. An example is given in Fig. 12.1.5.2 in which mercuric chloride has been used to replace zinc in thermolysin. Hg^{2+} complexes are commonly two-coordinate linear and four-coordinate tetrahedral. The most popular mercury reagents are given in Table 12.1.5.3. The covalent character in $Hg{-}L$ bonds, especially in the two-coordinate complexes, can cause solubility problems in aqueous solutions. However, an excess of an alkali metal salt (*e.g.* $HgI_2 + 2KI \rightarrow K_2HgI_4$) will often convert the compound to a more soluble anionic complex of the type HgX_4^{2-}, where X = Cl^-, Br^-, I^-, SCN^-, NCS^-, CN^-, SO_4^{2-}, oxalate^{2-}, NO_3^- or NO_2^-. In the presence of ammonium salts at high pH values, the cationic tetraammine complex, $Hg(NH_3)_4^{2+}$, tends to form. Variation in the charge on the aromatic groups of organomercurials can give rise to different substitution patterns.

Silver, used as the nitrate, tends to interact with cysteine or histidine (see Fig. 12.1.5.3). In the presence of ammonium sulfate, it probably reacts as the ammonia complex, $Ag(NH_3)_4^+$. Silver ions are less polarizing and less reactive than Hg^{2+} ions; thus they give similar derivatives but often with less disorder, as in glucagon (Sasaki *et al.*, 1975). Where the metal ion displaces a proton, Ag^+ will need to react at a higher pH than Hg^{2+}.

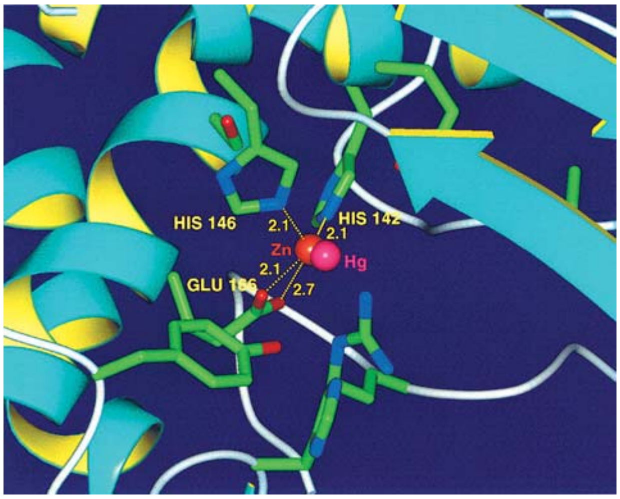

Figure 12.1.5.2
Mercuric ions replace zinc in thermolysin (3TLN). The mercuric ion is shown superposed on the parent crystal structure; notice that the mercuric ion is slightly displaced from the zinc position due to its larger ionic radius.

Table 12.1.5.4
The five most popular platinum derivatives

The first column gives the number of times the reagent has been used the analyses included in the heavy-atom data bank.

No.	Compound
287	Potassium tetrachloroplatinum(II)
61	Potassium tetranitritoplatinum(II)
58	Potassium tetracyanoplatinum(II)
57	Dichlorodiammineplatinum(II)
51	Potassium hexachloroplatinum(IV)

The class B metals *palladium*, *platinum* and *gold* form stable covalent complexes with soft ligands, such as chloride, bromide, iodide, ammonia, imidazole and sulfur groups. The stereochemistry of their complexes depends on the number of d electrons present. For instance, the d^{10} ion of Au(I) gives a linear coordination of two [*e.g.* $Au(CN)_2^-$], whereas d^8 ions of Pd(II), Pt(II) and Au(III) are predominantly square planar, giving cationic [*e.g.* $Pt(NH_3)_4^{2+}$], anionic [*e.g.* $Au(CN)_4^-$, $PtCl_4^{2-}$ and $PdCl_4^{2-}$] or neutral [*e.g.* $Pt(NH_3)_2Cl_2$] complexes. These may accept an additional ligand to give square pyramidal coordination or two ligands to give octahedral coordination. The additional ligands are normally more weakly bound. Pt(IV) has a d^6 configuration and forms stable octahedral complexes, such as $PtCl_6^{2-}$, with six equivalent covalently bound ligands.

The kinetic and thermodynamic stability of these complexes depends on the protein ligands, buffer, pH and salting in/out agent (Petsko *et al.*, 1978). Anionic groups do not readily react with anionic reagents, such as RS^-, but are attacked more readily by neutral nucleophiles such as RSH, R-imidazole or RNH_2. The inert cationic group $Pt(NH_3)_4^{2+}$ is most likely to form electrostatic complexes with anionic groups, such as carboxylate. The neutral $Pt(NH_3)_2Cl_2$ molecule, however, can penetrate into hydrophobic areas but requires a stronger nucleophile such as RS^-. In acidic and neutral solutions, $PtCl_4^{2-}$ reacts most commonly with methionine (Figs. 12.1.5.4 and 12.1.5.5), cystine (disulfide) (Fig. 12.1.5.6), N-termini and histidine to form stable complexes. However, methionine reacts faster than histidine. Thus, it is possible to use time as a variable to define specificity. The most popular platinum reagents are listed in Table 12.1.5.4.

In aqueous solution, the square-planar complex $AuCl_4^-$ is hydrolysed to $Au(OH)_4^-$ in about one hour, or in the presence of

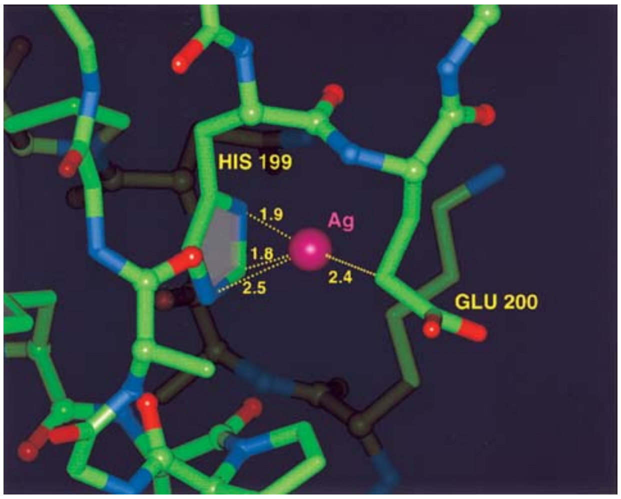

Figure 12.1.5.3
The binding of a silver ion to immunoglobulin Fab (2FB4). The positions of the ligands in the parent crystals are shown, and these must move in the complex to coordinate the silver ion.

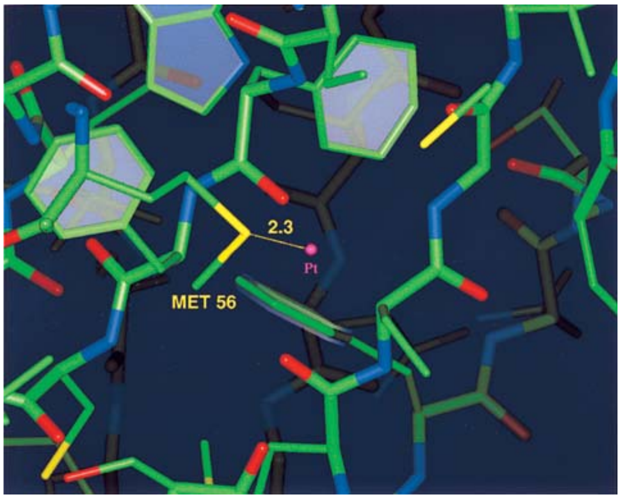

Figure 12.1.5.4
The binding of $PtCl_4^{2-}$ through a methionine in azurin (1AZU).

a protein, reduced to Au(I) by methionine. In ammonium sulfate it probably exists as $AuCl_3(NH_3)$, $AuCl_2(NH_3)_2^+$ and $Au(NH_3)_4^{3+}$. In contrast, $Au(CN)_2^-$ is more stable and normally binds electrostatically. However, on occasions at pH > 6.0, the $Au(CN)_2^-$ complex has bound to cysteine residues by nucleophilic displacement reactions.

Osmium resembles platinum in many ways and typically acts as a class B metal. It occurs in all oxidation states from 0 to VIII, but most usually in III, as in K_3OsCl_6; in IV, as in K_2OsCl_6; in VI, as in $K_2OsO_2(OH)_4$; and in VIII, as in osmium tetraoxide, OsO_4. Higher-oxidation-state compounds tend to be reduced to $OsO_2(OH)_2$ in most crystallization solutions and in the presence of ammonia or halide ion they can become further reduced to cationic or anionic complexes, such as $Os(NH_3)_6^{3+}$ or $OsCl_6^{2-}$. Anionic complexes may be substituted by histidine residues at pH > 7.0 or bound as ion pairs by histidine at pH < 7.0 or protonated amino groups. Cationic complexes tend to bind to negatively charged residues *via* electrostatic interactions.

Iridium is found in all oxidation states from II to VI but commonly exists in III, as in K_3IrCl_6, and IV, as in $(NH_4)_2IrCl_6$. Ir(III) is similar to *rhodium*(III) and is found in a variety of cationic, uncharged and anionic complexes. All Ir(III) complexes are kinetically inert, whereas most anionic complexes of Rh(III) are labile. Ir(IV) is commonly found as the hexahalo complexes IrX_6^{2-} (except iodine), which are also fairly kinetically inert. Cationic [*e.g.* $Ir(NH_3)_6^{3+}$], neutral (*i.e.* $IrCl_3$) and anionic (*i.e.* $IrCl_6^{2-}$) species have proved useful in forming derivatives of protein crystals.

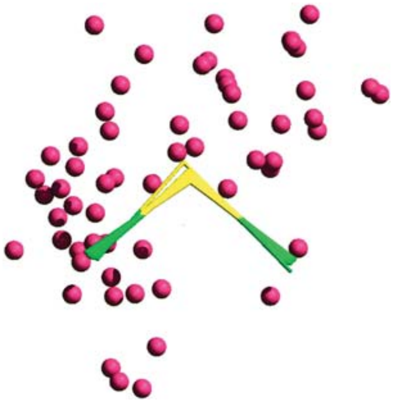

Figure 12.1.5.5
The relative positions of methionine side chains (carbon: green; sulfur: yellow) in the parent crystals to the binding of platinum (pink) of $PtCl_4^{2-}$. The methionine side chains have been least-squares fitted.

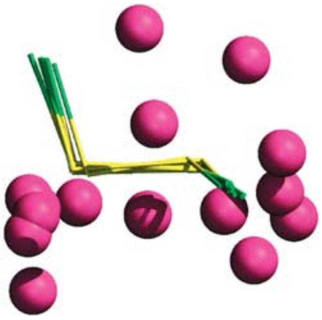

Figure 12.1.5.6

12.1.5.4. Electrostatic binding of heavy-atom anions

Positively charged groups of proteins, such as the α-amino terminus, ε-amino of lysine, guanidinium of arginine and imadazolium of histidine, may form ion pairs with heavy-atom anionic complexes. For example, HgI_4^{2-} and HgI_3^- can bind through electrostatic interactions. Anionic metal cyanide complexes tend to be more resistant to substitution and consequently interact electrostatically on most occasions. For example, $Pt(CN)_4^{2-}$ binds at several sites involving lysine or arginine residues in proteins (Fig. 12.1.5.7). $Pt(CN)_4^{2-}$ and $Au(CN)_2^-$ can act as inhibitors by binding at coenzyme phosphate sites.

12.1.5.5. Hydrophobic heavy-atom reagents

Since many heavy-atom reagents are hydrophilic, most interactions occur at the protein surface. However, substitution, addition or removal of the non-heavy-atom component(s) of the reagent can alter the hydrophilic–hydrophobic balance and lead to penetration of the core. For example, anionic complexes such as $HgCl_4^{2-}$ and $PbCl_6^{2-}$ are hydrophilic and would not normally enter the protein core, although organometallics, such as *R*HgCl

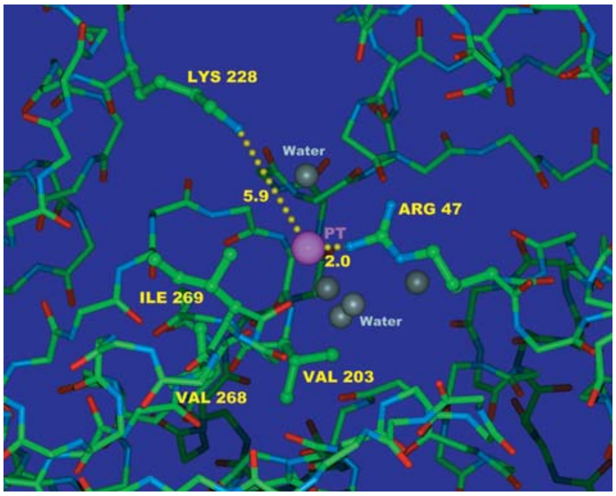

Figure 12.1.5.7
The binding of $Pt(CN)_4^{2-}$ to aldose dehydrogenase (8ADH).

and R_3PbCl (R = aliphatic or aromatic), are much more hydrophobic and can do so.

Hydrophobic organomercury compounds of the general formula $R$Hg$X$, where R is an aliphatic or aromatic organic group, react with sulfhydryls through displacement of X. When X is PO_4^{3-}, SO_4^{2-} or NO_3^-, the bond is ionic, making the formation of the cation $R\mathrm{Hg}^+$ easier. R is often chosen to be a small aliphatic group (*e.g.* CH_3, C_2H_5). However, the presence of a benzene ring enhances the stability of the heavy-atom reagent. Careful selection of the X group can assist penetration into the hydrophobic core. The hydrophobicity of X follows the order

$$PO_4^{3-} < NO_3^- < Cl < Br < I < R.$$

$R$Hg$R$ (R = aliphatic or aromatic) compounds also bind sulfhydryl residues in hydrophobic regions. The mechanism of reaction of methylphenylmercury with buried sulfhydryl groups may involve fast dissolution in the hydrophobic interior of the protein followed by a slow reaction with neighbouring sulfhydryl residues (Abraham *et al.*, 1983). They are difficult to prepare in aqueous solutions; an aprotic solvent, such as acetonitrile, can improve solubility, but this is not normally a problem in high concentrations of organic components, such as PEG, MPD or ethanol.

Inert gases were first used in the analysis of myoglobin. Schoenborn *et al.* (1965) discovered that the hydrophobic site that bound HgI_3^- also bound a xenon atom at 2.5 atmospheres. They proposed that this may be a general way of producing heavy-atom derivatives of proteins. Recently, there has been increasing interest in this idea, which has now been developed to produce well defined derivatives of a wide range of different proteins. Crystals are subjected to high gas pressures. Xenon requires about 10 atmospheres in order to get saturated binding sites. Krypton binds much less strongly and requires around 60 atmospheres. Since the binding of both inert gases is reversible, it is necessary to keep the protein crystals in a gaseous environment in a specialized pressure cell. Such pressure cells have been developed by Schiltz (1997) at LURE. Xenon binds to hydrophobic cavities, with little conformational change and a retention of isomorphism in crystals. Krypton binds at the same sites as xenon, but since it is lighter and needs higher pressure it has been exploited less by protein crystallographers. However, it has a well defined K edge at around 1 Å and so has attractions for multiple-wavelength anomalous dispersion.

12.1.5.6. Iodine

In addition to their use in isomorphous replacement, iodine derivatives of crystalline proteins have been prepared as tyrosine or histidine markers to assist main-chain tracing and to act as a probe for surface residues. The order of reactivity towards these reactive residues is

$$\mathrm{Tyr} > \mathrm{His} \gg \mathrm{Trp}.$$

I_3^-, I^-, I^+ and I_2 can be generated by several different methods. An equimolar solution of KI/I_2 or NaI/I_2 in 5% (v/v) ethanol/water solution is often used to generate the anionic species I_3^- and I^-. An oxidizing agent, such as chloramine T, can be added to KI, typically in a concentration ratio of 1:50; alternatively, polystyrene beads derivatized with *N*-chlorobenzene sulfonamide can be used with NaI. Similarly, the addition of excess KI to ICl or OI^- will generate I_3^-, I^- and I^+. To avoid oxidation of iodine solutions, the pH should be less than 5.0. To avoid cracking the crystals, it may be necessary to increase the iodine concentration very slowly and to wash the derivatized crystals in the mother liquor in order to remove free I_2. Mono- or di-iodination of tyrosines can cause disruption of the protein structure either because of the larger size or the breaking of hydrogen bonds due to lowering of the pK_a of the phenolic hydroxyl.

12.1.5.7. Polynuclear reagents

The structure determination of large multicomponent systems such as the 50S ribosomal subunit (Yonath *et al.*, 1986) or the nucleosome core particle (O'Halloran *et al.*, 1987) requires the addition of reagents with a greater number of electrons, preferably in a compact polynuclear structure. Such reagents may be either cluster compounds or multimetal centres having metal–metal bonds.

Polynuclear reagents should preferably be covalently bound to one or a few specific sites, either first in solution or later in the crystals. Spacers of differing length can be inserted into the reagent to increase accessibility. Their low solubility in aqueous solutions can often be overcome by dissolving them in an apolar solvent (*e.g.* acetonitrile). Tetrakis(acetoxymercurio)methane (TAMM) and di-*m*-iodobis(ethylenediamine)diplatinum(II) nitrate (PIP) have better solubility in aqueous solutions than other polynuclear heavy-atom compounds.

Polynuclear heavy-atom reagents give an enhanced signal-to-noise ratio in low-resolution MIR studies, but this advantage is offset by the fall-off in scattering amplitude that arises from interference of diffracted waves at higher resolution. In the nucleosome core particle, the scattering reached 50% of its zero-angle value at 7.0 Å, while the relative drop for a single heavy atom was 10% (O'Halloran *et al.*, 1987). Cluster and multimetal reagents that have been successfully employed in protein structure determinations have been reviewed by Thygesen *et al.* (1996).

12.1.6. Metal-ion replacement in metalloproteins

The metal-ion cofactor can sometimes be displaced by dialysis or diffusion by a heavy-atom solution, but usually the cofactor is first removed by a chelating agent (*e.g.* EDTA) or by acidification. These are best carried out on the crystals. Alternatively, the metal can be substituted by biosynthesis of the metalloprotein under enriched conditions of the substituting metal, an approach which has been successful in displacing zinc with cobalt and other lighter metals.

The metal ions are best substituted by a metal of similar character and radius. Thus, calcium is an A-group metal which prefers ligands containing oxygen atoms that may originate from carboxylic, carboxyamide, hydroxyl, main-chain carbonyl groups and water molecules. Divalent alkaline earth metal ions (*e.g.* Sr^{2+}, Ba^{2+}) or trivalent lanthanide ions can bind at calcium sites but can give very different coordination geometry and stability. Nd^{3+} and Sm^{3+} can displace some Ca^{2+} ions with negligible change in structure (Fig. 12.1.6.1). On the other hand, zinc has a relatively small ionic radius and is more polarizing. Structural zinc atoms are often tetrahedrally coordinated by cysteine residues, while those at active sites frequently bind histidine, often in association with a water molecule and/or carboxylate ligands. Cadmium or mercury can replace zinc, but often with a conformational change leading to lack of isomorphism.

12.1.7. Analogues of amino acids

Attempts to replace amino acids by heavy-atom substituted synthetic analogues with a similar charge and shape have not

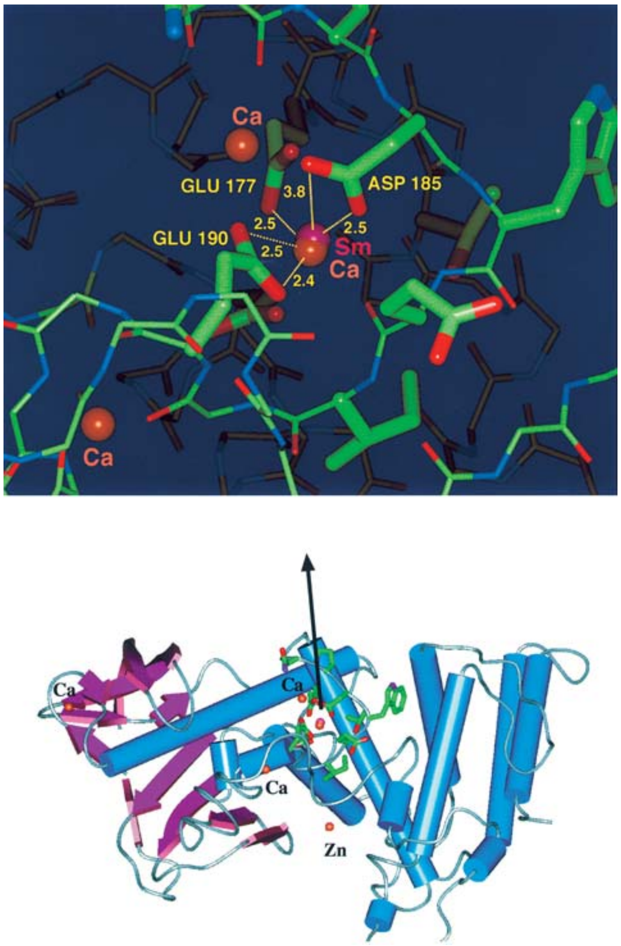

Figure 12.1.6.1
The displacement of calcium by samarium in thermolysin. The samarium of the heavy-atom derivative is shown superposed on the parent crystal structure.

proved successful in large proteins, although a selenocystine was used successfully in the analysis of oxytocin (Wood *et al.*, 1986). However, the production of proteins labelled by selenium using biological substitution of selenomethionine (SeMet) for methionine (Hendrickson, 1985) has been stimulated by multiple-wavelength anomalous dispersion (MAD) (Hendrickson *et al.*, 1990). Methionine biosynthesis is blocked in the cells in which the protein is produced and SeMet is substituted for Met in the growth medium. The generality of the labelling scheme for proteins is the root of its success, as discussed by Doublié (1997).

SeMet has been incorporated into proteins expressed in *Escherichia coli* strains that are auxotrophic for Met [strain DL421 (Hendrickson *et al.*, 1990); strain B834 (Leahy *et al.*, 1994); strain LE392 (Ceska *et al.*, 1996)]. Nearly complete incorporation has also been reported in non-auxotrophic bacterial strains, *E. coli* strain XA90 (Labahn *et al.*, 1996), in a mammalian cell line (Lustbader *et al.*, 1995) and in baculovirus-infected insect cells (Chen & Bahl, 1991). Usually, somewhat higher than normal concentrations of disulfide reducing agents, such as dithiothreitol or mercaptoethanol, are sufficient to protect SeMet from air oxidation to the selenoxide, although crystallization in an inert atmosphere may be necessary. Proteins usually have SeMet substituted for Met at levels approaching 100%. The cells are viable and the proteins are functional.

Site-directed mutagenesis offers an alternative approach for the introduction of specific heavy-atom binding sites. A common procedure is to replace residue(s) in the variable part of the primary structure with cysteine. The selection of the residue to mutate in a protein of unknown structure remains a challenge.

Although selenocysteine is toxic to cells, cysteine auxotrophic strains, in which proteins can be synthesized with the seleno derivative, have been developed (Miller, 1972; Muller *et al.*, 1994). The bacteria are grown under limiting amounts of cysteine with no other sulfur source. They are induced for 10 min and then resuspended in selenocysteine for a 3 h incubation. The protein is purified with a reducing agent. In general, the substitution at the selenocysteine seems to be less satisfactory than selenomethionine, with occupancy often as low as 20%.

Budisa *et al.* (1997) have experimented on incorporating a range of novel amino-acid analogues using *in vitro* suppression. This is achieved by suppressing the stop colons and engineering tRNA synthases to incorporate the analogue. Possible candidates are telluromethionine, 5-bromotryptophan, 5-iodotryptophan, selenotryptophan and tellurotryptophan. The bioincorporation of TeMet into derivatized crystals did not greatly affect their stability in buffer solutions and to X-radiation. Isomorphism was maintained despite the C—Te bond being longer than C—Se or C—S. TeMet crystals are not as suitable for MAD analysis as SeMet crystals due to the 0.3 Å absorption edge of tellurium. The method is restricted to methionine residues located in the hydrophobic regions, since solvent accessibility may cause undefined chemical reactions with the highly reactive C—Te side chain. Thus the protein must be expressed in the folded form.

12.1.8. Use of the heavy-atom data bank to select derivatives

The heavy-atom data bank is probably best exploited by first investigating the most commonly used heavy-atom reagents with a view to obtaining mercury, platinum and uranyl derivatives that tend to bind at different sites. The most common reagents (Table 12.1.5.1) can first be selected and tested for suitability in terms of amino-acid sequence, pH, buffer and salt. If there are many sulfhydryls, several mercurials might be exploited, or if there are several methionines, other platinum agents might be investigated. A high pH would argue against use of uranyl due to the insolubility of hydroxides; the presence of ammonium sulfate would argue for as low a pH as possible. The presence of citrate would imply changing the buffer for acetate if A-group metals, such as uranium or lanthanides, were to be used.

For each heavy-atom agent, the conditions of its previous use can be checked against the conditions of crystallization in the current study. Conversely, the database can be interrogated for reagents that have been used in similar conditions. In each case, derivatives that maximize the variety of ligands should be exploited.

The time of soak should be first set according to previous experience indicated in the database. However, the progress of heavy-atom substitution needs to be monitored by checking for change of colour, transparency or cracking. If cracking and disruption of the crystals occurs quickly, a less reactive reagent can be tried, and, conversely if substitution is insufficient, a more reactive reagent can be tried. If there are several cysteines, different derivatives can be obtained with mercurials of different size and hydrophobicity. In each circumstance, the data bank should provide useful information to assist in choosing reagents.

Please keep information about the heavy-atom binding sites and the heavy-atom structure-factor amplitudes. They should be submitted to the Protein Data Bank.

We thank all those who have generously sought out and sent us details of the heavy-atom binding sites in their derivatives, and the ICRF and the Wellcome Trust for support.

Chapter 12.2. Locating heavy-atom sites

M. T. Stubbs and R. Huber

12.2.1. The origin of the phase problem

Once a native data set has been collected, the next task is the solution of the structure. There is one major hurdle: the phase problem. To study objects at the atomic level, we must utilize waves with a wavelength in the ångström range, *i.e.* X-radiation. X-rays interact with electrons and so provide an image of the electron distribution of the sample. Unfortunately, X-rays are refracted by matter only very weakly, and so it is not possible to construct a lens to view molecules at atomic dimensions.[1]

As shown in Chapter 2.1, the diffraction $F(\mathbf{S})$ obtained from an electron-density distribution $\rho(\mathbf{r})$ is given by

$$F(\mathbf{S}) = \textstyle\int \rho(\mathbf{r}) \exp\{2\pi i \mathbf{r} \cdot \mathbf{S}\}\, \mathrm{d}^3\mathbf{r},$$

where $\mathbf{S}$ is perpendicular to the scattered wave and $|\mathbf{S}| = 2\sin\theta/\lambda$; θ is the scattering angle and λ is the wavelength. The diffraction pattern is a *Fourier transform* of the electron density. If we have a crystal with cell parameters a, b and c, then the Laue diffraction conditions require that $\mathbf{S}$ lies on a reciprocal lattice such that $\mathbf{S} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$, where $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$ are the reciprocal-lattice vectors, and h, k and l are the integer indices of the diffracted beam.

$$F(hkl) = V \sum_{xyz} \rho(xyz) \exp\{2\pi i(hx + ky + lz)\},$$

where V represents the volume of the unit cell, and x, y and z are the fractional coordinates within that cell in the directions of $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$.

Since the diffraction pattern is a Fourier transform of the electron density, it follows that the electron density is an inverse Fourier transform of the diffraction pattern:

$$\rho(\mathbf{r}) = \textstyle\int F(\mathbf{S}) \exp\{-2\pi i \mathbf{r} \cdot \mathbf{S}\}\, \mathrm{d}^3\mathbf{S},$$

$$\rho(xyz) = (1/V) \sum_{hkl} F(hkl) \exp\{-2\pi i(hx + ky + lz)\}.$$

Thus it should be mathematically straightforward to calculate the electron density from the diffraction pattern. This is, unfortunately, not the case. The function $F(\mathbf{S})$ describing the diffracted rays is a complex function with a *magnitude* $|F(\mathbf{S})|$ and a *phase* $\varphi(\mathbf{S})$. The diffraction experiment measures the *intensities* $I(\mathbf{S})$, however; the relationship between $I(\mathbf{S})$ and $F(\mathbf{S})$ is:

$$I(\mathbf{S}) = F^*(\mathbf{S}) \cdot F(\mathbf{S}) = |F(\mathbf{S})|^2,$$

where $F^*(\mathbf{S})$ is the complex conjugate of $F(\mathbf{S})$. The measured intensities are related directly to the magnitudes of the diffracted beams; the phase information, however, is lost (Fig. 12.2.1.1): this is the origin of the *phase problem*.

There are essentially four ways of overcoming the phase problem (Fig. 12.2.1.2):

(1) the use of isomorphous replacement to influence the diffraction pattern, thereby revealing information about the phases (this chapter);

(2) Patterson search techniques, which in essence allow modelling of the phase distribution of an unknown crystal based upon that of a known molecule (Part 13);

(3) the use of anomalous dispersion, which shifts the imaginary component of $F(\mathbf{S})$, allowing an experimental measurement of the phase (Part 14); and

(4) direct methods, which make use of probabilistic relationships between different diffracted rays (Part 16).

The method of isomorphous replacement, by which the first macromolecular structures were solved (Green *et al.*, 1954), remains the most widely used technique for *ab initio* structure

Intensities
$I(\mathbf{S}) = F^*(\mathbf{S})\cdot F(\mathbf{S}) = |F(\mathbf{S})|^2$
$P(\mathbf{u}) = \frac{1}{\kappa}\int I(\mathbf{S})\exp(2\pi i\mathbf{u}\cdot\mathbf{S})\,\mathrm{d}^3\mathbf{S}$
$I(\mathbf{S}) = \kappa\int P(\mathbf{u})\exp(-2\pi i\mathbf{u}\cdot\mathbf{S})\,\mathrm{d}^3\mathbf{u}$

Figure 12.2.1.1
Relationships in diffraction space. The diffraction pattern of an object is the Fourier transform of the electron density, consisting of both amplitudes and phases. What we measure in an X-ray diffraction experiment, however, are the diffracted intensities; the phase information is lost. The Fourier transform of the intensities results in the Patterson map, which is related to the electron density as follows. For any two atoms in the structure, the vector between them, centred at the origin, has a value corresponding to the product of their densities. Thus, the red atom and the yellow atom result in the orange cross vectors, the red and blue atoms result in the magenta cross vectors, and the yellow and blue atoms result in green cross vectors. As each atom has a 'cross vector' to itself, a large peak is found at the origin; the Patterson map is centrosymmetric.

---

[1] This is not strictly true, due to advances in electron microscopy (see Part 19); however, this method has yet to find the universality enjoyed by X-ray crystallography.

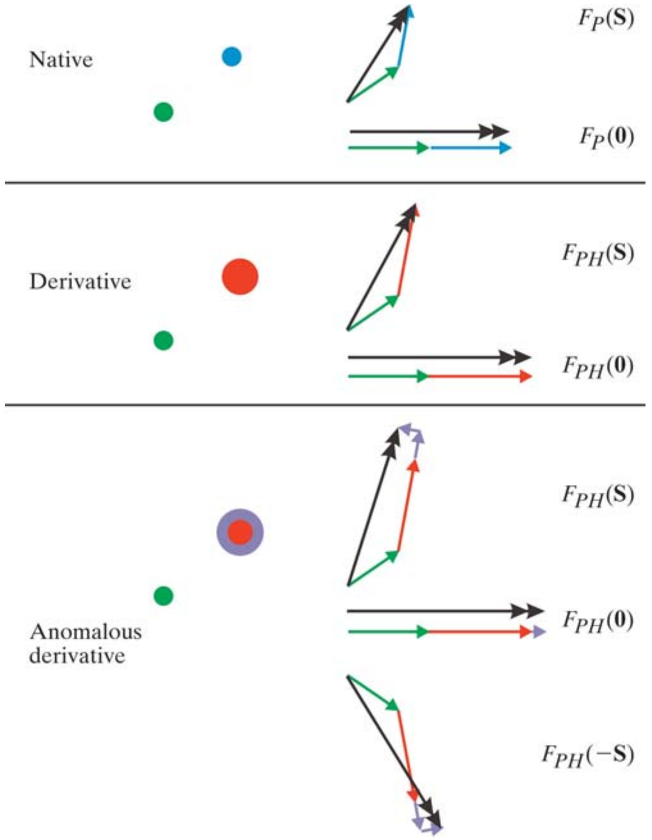

Figure 12.2.1.2
The effect of introducing a heavy atom or anomalous scatterer. The native two-atom structure gives rise to two diffraction vectors (green and blue) of equal magnitude but different phase (see Chapter 2.1), with a resultant diffraction vector F_P (black). Isomorphous replacement of the blue atom by the larger red one gives rise to a diffraction vector of greater magnitude but equivalent phase (red), causing a change in the resultant magnitude F_{PH} (and hence the intensity) *and* in the phase. Introduction of an anomalous scatterer results in a phase shift (lilac) of the diffraction vector, resulting in differing amplitudes and phases for $F_{PH}(\mathbf{S})$ and $F_{PH}(-\mathbf{S})$.

determination, although the availability of synchrotrons, with their facility for selecting a desired wavelength, and molecular-biology techniques that allow the direct introduction of anomalous scatterers, such as selenium or tellurium, into the protein of interest (Hendrickson *et al.*, 1990; Budisa *et al.*, 1997) have proven that multiple anomalous dispersion is an exceptionally powerful technique for the solution of novel structures. Patterson search techniques (Rossmann, 1972) are ideal if a similar macromolecular structure is already known, while direct methods are more-or-less confined to very high resolution data (Sheldrick, 1990).

In order to obtain phase information from isomorphous replacement (or from anomalous dispersion), it is necessary to locate the atomic positions of the heavy-atom (or anomalous) scatterers.

Figure 12.2.2.1
The Patterson map with symmetry. When the crystal unit cell contains more than one molecule, then additional cross vectors will be formed between differing molecules. If these are related by crystallographic symmetry, there is a geometrical relationship between cross peaks. In this diagram, the peaks of Fig. 12.2.1.1 are supplemented by those between atoms of symmetry-related molecules. The red, yellow and blue peaks of the resulting Patterson function represent those between same atoms (*i.e.* red to red, yellow to yellow and blue to blue) related by symmetry. These peaks are found on a Harker section.

12.2.2. The Patterson function

Although the set of measured intensities contains no information regarding the phases, the Fourier transform of the intensities, the so-called Patterson function, contains valuable information. Patterson (1934) showed that the inverse Fourier transform of the intensity,

$$P(uvw) = (1/V)\sum_{hkl} I(hkl)\exp\{-2\pi i(hu+kv+lw)\},$$

is related to the electron density by

$$P(\mathbf{u}) = \textstyle\int \rho(\mathbf{r})\rho(\mathbf{r}+\mathbf{u})\ \mathrm{d}^3\mathbf{r}.$$

The Patterson function $P(\mathbf{u})$ is an autocorrelation function of the density. For every vector $\mathbf{u}$ that corresponds to an interatomic vector, $P(\mathbf{u})$ will contain a peak (Fig. 12.2.1.1). These are some properties of the Patterson function:

(1) Every atom makes an 'interatomic vector' with itself, and therefore the *origin peak*, $P(\mathbf{0}) = \sum \rho^2(\mathbf{r})$, dominates the Patterson function. This origin peak can be 'removed' through subtraction of the average intensity from $I(hkl)$ before Fourier transformation.
(2) For every vector between $\rho_i(\mathbf{r}_i)$ and $\rho_j(\mathbf{r}_j)$, the same value (*i.e.* their product) is found for $\rho_j(\mathbf{r}_j)$ to $\rho_i(\mathbf{r}_i)$, and so the Patterson map is *centrosymmetric*.
(3) For a structure consisting of n atoms, there are $n(n-1)/2$ cross vectors, and so the Patterson function is extremely crowded.

For simple crystals, the Patterson map can be used to solve the structure directly. For macromolecular structures, the Patterson map provides a vehicle for solving the phase problem.

If the crystal contains rotational symmetry elements, then the cross vectors between $\rho_i(\mathbf{r}_i)$ and its symmetry mate lie on a plane perpendicular to the symmetry axis – the *Harker section* (Harker, 1956). By way of example, the space group $P2_1$ has two symmetry-related positions (Fig. 12.2.2.1),

$$(x, y, z) \text{ and } (-x, y + \tfrac{1}{2}, -z).$$

Cross vectors between symmetry-related points will therefore have the form

$$(2x, \tfrac{1}{2}, 2z),$$

i.e. all cross vectors lie on the plane $v = \frac{1}{2}$. For space group $P2_12_12_1$, the general coordinates

$$(x, y, z), (x + \tfrac{1}{2}, -y + \tfrac{1}{2}, -z), (-x + \tfrac{1}{2}, -y, z + \tfrac{1}{2}),$$
$$(-x, y + \tfrac{1}{2}, -z + \tfrac{1}{2})$$

give rise to cross vectors

$$(\tfrac{1}{2}, 2y + \tfrac{1}{2}, 2z), (2x + \tfrac{1}{2}, 2y, \tfrac{1}{2}), (2x, \tfrac{1}{2}, 2z + \tfrac{1}{2}),$$

i.e. there are three Harker sections: $u = \frac{1}{2}$, $v = \frac{1}{2}$ and $w = \frac{1}{2}$. Peaks occurring on the Harker sections must reduce to a self-consistent set of coordinates (x, y, z), allowing reconstruction of the atomic positions.

If we have two isomorphous (see below) data sets F_{PH} and F_P, then the difference in the two Patterson functions,

$$P_{PH} - P_P = \textstyle\int [F_{PH}^2(\mathbf{S}) - F_P^2(\mathbf{S})] \exp\{-2\pi i \mathbf{r} \cdot \mathbf{S}\} \, \mathrm{d}^3\mathbf{S},$$

will deliver information about the heavy-atom structure. Such a difference function gives rise to non-negligible peaks arising from interference between the F_H and F_P terms, however (Perutz, 1956). Rossmann (1960) showed that these interference terms could be reduced through calculation of the modified Patterson function

$$P_H = \textstyle\int [F_{PH}(\mathbf{S}) - F_P(\mathbf{S})]^2 \exp\{-2\pi i \mathbf{r} \cdot \mathbf{S}\} \, \mathrm{d}^3\mathbf{S}.$$

In the case of a single-site derivative, peaks should occur only at the Harker vectors corresponding to the heavy-atom position. Even so, there is a choice of positions for the heavy atom: *e.g.*, in the $P2_12_12_1$ case, coordinates $(\pm x + \xi, \pm y + \nu, \pm z + \zeta)$, where ξ, ν and ζ can each take the value 0 or 1/2, will all give rise to the same Harker vectors. This in itself is not a problem, relating to equivalent choices of origin and of handedness, but has important ramifications for multisite derivatives or multiple isomorphous replacement (see below).

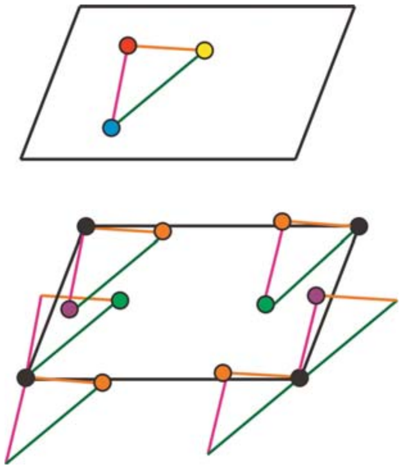

Figure 12.2.2.2
The vector superposition method. The Patterson map of Fig. 12.2.1.1 can be regarded as the superposition of the structure (and its inverse), with each of its atoms placed alternately at the origin. By shifting each peak of the Patterson function to the origin and calculating the correlation of all remaining peaks with the unshifted map, it is possible to deconvolute the Patterson function.

If there is more than one site, then there will be two sets of peaks: one set corresponding to the Harker sections (self-vector set) and one set corresponding to the difference vectors between different heavy-atom sites (the cross-vector set). In this case, the choice of one heavy-atom position (x_{H1}, y_{H1}, z_{H1}) determines the origin and the handedness to which all other peaks *must* correspond. Thus, in the $P2_12_12_1$ example, only one cross vector will occur for

$$(x_{h1} \pm x_{h2} + \xi, y_{h1} \pm y_{h2} + \nu, z_{h1} \pm z_{h2} + \zeta).$$

An alternative to the Harker-vector approach is Patterson-vector superposition (Sheldrick *et al.*, 1993; Richardson & Jacobson, 1987). The Patterson map contains several images of the structure that have been shifted by interatomic vectors (Fig. 12.2.2.2). If this structure is relatively simple (as is to be hoped for in a 'normal' heavy-atom derivative), then it should be possible to deconvolute the superimposed structures by vector shifts (Buerger, 1959).

12.2.3. The difference Fourier

Once the heavy-atom positions have been found, they can be used to calculate approximate phases and Fourier maps. Ideally, difference Fourier maps calculated with phases from a single site should reveal the other positions determined from the Harker search procedure. This ensures that all heavy-atom positions correspond to a single origin and hand. Similarly, phases calculated from derivative $H1$ should reveal the heavy-atom structure for derivative $H2$. Merging and refinement of all phase information will result in a phase set that can be used to solve the structure.

12.2.4. Reality

12.2.4.1. Treatment of errors

Until now, we have dealt with cases involving perfect data. Although this ideal may now be attainable using MAD techniques, this is not necessarily the usual laboratory situation. In the first place, it is necessary to scale the derivative data F_{PH} to the native F_P. One of the most common scaling procedures is based on the expected statistical dependence of intensity on resolution (Wilson, 1949). This may not be particularly accurate when only low-resolution data are available, in which case a scaling through equating the Patterson origin peaks of native and derivative sets may provide better results (Rogers, 1965).

A model to account for errors in the data, determination of heavy-atom positions *etc.* was proposed by Blow & Crick (1959), in which all errors are associated with $|F_{PH}|_{\rm obs}$ (Fig. 12.2.4.1); a more detailed treatment has been provided by Terwilliger & Eisenberg (1987). Owing to errors, the triangle formed by F_P, F_{PH} and F_H fails to close. The *lack of closure error* ε is a function of the calculated phase angle φ_P:

$$\varepsilon(\varphi_P) = |F_{PH}|_{\rm obs} - |F_{PH}|_{\rm calc}.$$

Once an initial set of heavy-atom positions has been found, it is necessary to refine their parameters (x, y, z, occupancy and thermal parameters). This can be achieved through the minimization of

$$\sum_{\mathbf{S}} \varepsilon^2 / E,$$

where E is the estimated error $(\simeq \langle (|F_{PH}|_{\rm obs} - |F_{PH}|_{\rm calc})^2 \rangle)$ (Rossmann, 1960; Terwilliger & Eisenberg, 1983). This procedure is safest for noncentrosymmetric reflections (φ restricted to 0 or π) if enough are present. Phase refinement is generally monitored by three factors:

$$R_{\rm Cullis} = \sum\|F_{PH} + F_P| - |F_H|_{\rm calc}|\big/\sum|F_{PH} - F_P|$$

for noncentrosymmetric reflections only; acceptable values are between 0.4 and 0.6;

$$R_{\rm Kraut} = \sum\||F_{PH}|_{\rm obs} - |F_{PH}|_{\rm calc}|\big/\sum|F_{PH}|_{\rm obs},$$

which is useful for monitoring convergence; and the

$$\text{phasing power} = \sum|F_H|_{\rm calc}/\sum\||F_{PH}|_{\rm obs} - |F_{PH}|_{\rm calc}|,$$

which should be greater than 1 (if less than 1, then the phase triangle cannot be closed *via* F_H).

The resulting phase probability is given by

$$P(\varphi_P) = \exp\{-\varepsilon^2(\varphi_P)/2E^2\}.$$

The phases have a minimum error when the *best phase* $\varphi_{\rm best}$, *i.e.* the centroid of the phase distribution,

$$\varphi_{\rm best} = \textstyle\int \varphi_P P(\varphi_P)\,{\rm d}\varphi_P,$$

is used instead of the most probable phase. The quality of the phases is indicated by the *figure of merit m*, where

$$m = \textstyle\int P(\varphi_P)\exp(i\varphi_P)\,{\rm d}\varphi_P\big/\int P(\varphi_P)\,{\rm d}\varphi_P.$$

A value of 1 for m indicates no phase error, a value of 0.5 represents a phase error of about 60°, while a value of 0 means that all phases are equally probable.

The *best Fourier* is calculated from

$$\rho_{\rm best}(\mathbf{r}) = (1/V)\sum_{\mathbf{S}} m|F_P(\mathbf{S})|\exp\{i\varphi_{P{\rm best}}(\mathbf{S})\},$$

where the electron density should have minimal errors.

12.2.4.2. Automated search procedures

If the derivative shows a high degree of substitution, then the Harker sections become more difficult to interpret. Furthermore, Terwilliger *et al.* (1987) have shown that the intrinsic noise in the difference Patterson map increases with increasing heavy-atom substitution. It is at this stage that automated procedures are invaluable.

One such automated procedure is implemented in *PROTEIN* (Steigemann, 1991). The unit cell is scanned for possible heavy-atom sites; for each search point (x, y, z), all possible Harker vectors are calculated, and the difference-Patterson-map values at these points are summed or multiplied. As the origin peak dominates the Patterson function, this region is set to zero. The resulting correlation map should contain peaks at all possible heavy-atom positions. The peak list can then be used to find a set of consistent heavy-atom locations through a subsequent search for difference vectors (cross vectors) between putative sites. It should be possible to locate all major and minor heavy-atom sites through repetition of this procedure. A similar strategy is adopted in the program *HEAVY* (Terwilliger *et al.*, 1987), but sets of heavy-atom sites are ranked according to the probability that the peaks are not random. The program *SOLVE* (Terwilliger & Berendzen, 1999) takes this process a stage further, where potential heavy-atom structures are solved and refined to generate an (interpretable) electron density in an automated fashion.

The search method can also be applied in reciprocal space, where the Fourier transform of the trial heavy-atom structure is calculated, and the resulting $F_{H{\rm calc}}$ is compared to the measured differences between derivative and native structure-factor amplitudes (Rossmann *et al.*, 1986). In the programme *XtalView* (McRee, 1998), the correlation coefficient between $|F_H|$ and $|F_{PH} - F_P|$ is calculated, whilst a correlation between F_H^2 and $(F_{PH} - F_P)^2$ is used by Badger & Athay (1998). Dumas (1994*b*,*c*) calculates the correlation between $|F_{H{\rm calc}}|^2$ and $|F_{H{\rm estimated}}|^2$, based on the estimated lack of isomorphism.

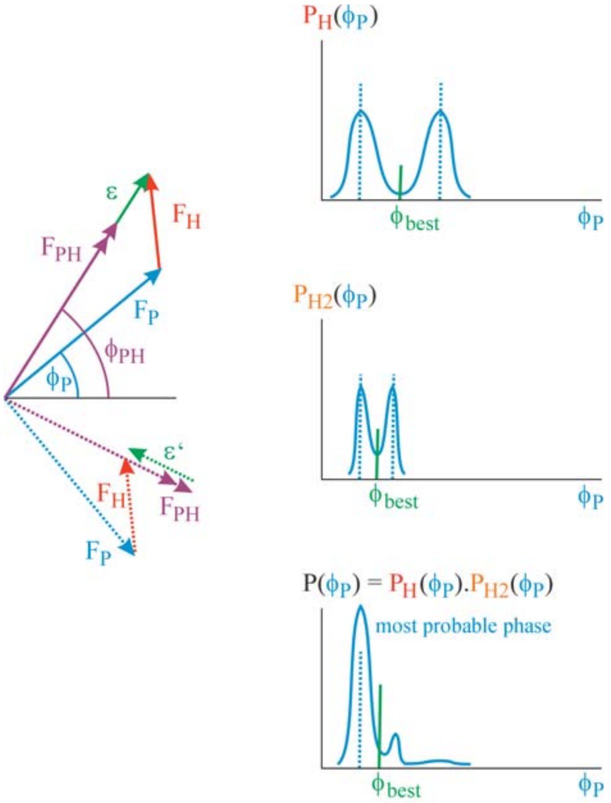

Figure 12.2.4.1

The treatment of phase errors. The calculated heavy-atom structure results in a calculated value for both the phase and magnitude of F_H (red). According to the value of φ_P, the triangle F_P–F_H–F_{PH} will fail to close by an amount ε, the lack of closure (green). This gives rise to a phase distribution which is bimodal for a single derivative. The combined probability from a series of derivatives has a most probable phase (the maximum) and a best phase (the centroid of the distribution), for which the overall phase error is minimum.

Vagin & Teplyakov (1998) have reported a heavy-atom search based on a reciprocal-space translation function. In this case, low-resolution peaks are not removed but weighted down using a Gaussian function. Potential solutions are ranked not only according to their translation-function height, but also through their phasing power, which appears to be a stronger selection criterion.

All these searches are based upon the sequential identification of heavy-atom sites and their incorporation in a heavy-atom partial structure. Problems arise when bogus sites influence the search for further heavy-atom positions. In an attempt to overcome this problem, the heavy-atom search has been reprogrammed using a genetic algorithm, with the Patterson minimum function as a selection criterion (Chang & Lewis, 1994). This approach has the potential to reveal all heavy-atom positions in one calculation, and tests on model data have shown it to be faster than traditional sequential searches.

12.2.5. Special complications

12.2.5.1. Lack of isomorphism

This problem is by far the most common in protein crystallography. An isomorphous derivative is one in which the crystalline arrangement has not been disturbed by derivatization. An early study of Crick & Magdoff (1956) proposed a rule of thumb that a change in any of the cell dimensions by more than around 5% would result in a lack of isomorphism that would defeat any attempt to locate the heavy-atom positions or extract useful phase information. Lack of isomorphism can, however, be more subtle; sometimes a natural variation in the native crystal form may occur, resulting in poor merging statistics of data obtained from different crystals. Coupling this variation with commonly observed structural changes upon heavy-atom binding can provide a considerable barrier to obtaining satisfactory phases. Dumas (1994*a*) has provided a theoretical consideration of this problem.

One practical approach is to collect native and derivative data sets from the same crystal, a technique that has been successful in the structure determination of cyclohydrolase (Nar *et al.*, 1995), proteosome (Löwe *et al.*, 1995) and a number of other proteins. Nonisomorphism can be used, however. In the structure solution of carbamoyl sarcosine hydrolase (Romao *et al.*, 1992), derivatives fell into two (related) crystalline classes. By judicious use of two 'native' crystal forms, heavy-atom positions could be obtained in each of the two classes. Phasing and resultant averaging between the two classes provided an interpretable electron density. In the case of ascorbate oxidase (Messerschmidt *et al.*, 1989), multiple isomorphous replacement failed to provide an interpretable density. It was possible, however, to place the initial density into a second crystal form, which in turn provided phases of sufficient quality to determine heavy-atom sites in derivatives of the second form. Phase-combination and density-modification techniques in the two crystal forms allowed the solution of the structure.

12.2.5.2. Space-group problems

Although the macromolecular crystallographer is rarely confronted with the problems facing their small-molecule colleagues with regard to determining the correct space group, the simplified heavy-atom structure may often throw some surprises. Certain pseudosymmetries may become 'exact' for the heavy-atom difference Patterson map. Thus, cross peaks between different heavy atoms may occur on a Harker section (or 'pseudo-Harker section'), complicating interpretation of the Patterson map. Such was the case with azurin (Adman *et al.*, 1978; Nar *et al.*, 1991), where the heavy-atom structure gave rise to a pseudo-homometric Patterson function, *i.e.* one in which two possible (nonequivalent) choices were available for the heavy-atom structure, only one of which was correct. This arose from a pseudo-centring of the lattice that became almost exact for the heavy-atom structure.

In the case of human NC1 (Stubbs *et al.*, 1990), all heavy-atom derivatives appeared to lie on or near the crystallographic twofold axis. This resulted in a partially centrosymmetric heavy-atom structure that failed to deliver sufficient phase information for noncentrosymmetric reflections. To check for problems with the native data set, anomalous difference Patterson maps {coefficients $[F_{PH}(\mathbf{S}) - F_{PH}(-\mathbf{S})]^2$} were calculated. Coincidence of the peaks obtained from conventional and anomalous Patterson syntheses showed that the heavy-atom positions were correct, but unfortunately did not lead to a structure solution.

12.2.5.3. High levels of substitution; noncrystallographic symmetry

Most problematic are the cases where many heavy atoms have become incorporated in the asymmetric unit. Not only does this cause difficulties in the scaling of derivative to native data, but also the large number of peaks results in ambiguities in the solution of the Patterson function. In such cases, it may be necessary to obtain primary phase information from a different source (such as, for example, another low-substitution-site derivative). One important subclass of high-level substitution is when the native asymmetric unit contains several copies of a single molecule (noncrystallographic symmetry or NCS).

A major problem in locating complex noncrystallographic axes is that the geometrical relationship between NCS peaks in the Patterson map is nontrivial. Under certain conditions, NCS results in a recognizable local symmetry within the Patterson map (Stubbs *et al.*, 1996). In many cases, however, these conditions (that the NCS axes of crystallographic symmetry-related molecules are parallel) are not fulfilled. Under such circumstances, all heavy-atom sites (including all crystallographic symmetry-related positions) must be checked carefully with the rotation function in order to pinpoint the NCS axis. This is relatively trivial for low-order NCS (twofold, threefold), but becomes increasingly complicated for higher orders. It should also always be borne in mind that the heavy-atom positions might not necessarily follow the NCS constraints due to crystal packing. If there is reason to suspect that sites are related by local symmetry, then the orientation of this axis can be used in the initial Harker searches; in practice, however, such searches are extremely sensitive to the correct orientation of the axis.

In the case of high-order NCS (such as, *e.g.*, with icosahedral virus structures or symmetric macromolecular complexes), an alternative approach to the usual initial Harker-vector search can be provided by the self-rotation function. Knowledge of the orientation of the NCS axis (from the rotation function) can be used to determine the relative positions of heavy atoms to the NCS axis (Argos & Rossmann, 1976; Arnold *et al.*, 1987; Tong & Rossmann, 1993). The orientation can be refined and the resulting peaks can be used as input in a subsequent translation search of the Harker sections.

PART 13. MOLECULAR REPLACEMENT

Chapter 13.1. Noncrystallographic symmetry

D. M. Blow

13.1.1. Introduction

Excellent reviews of noncrystallographic symmetry exist. The subject is also discussed in Volume B of this series (Rossmann & Arnold, 2001). Other important reviews include those by Rossmann (1990), Lawrence (1991) and Rossmann (1995). A volume produced for a Daresbury Study Weekend (Dodson *et al.*, 1992) has many interesting chapters.

In this introductory chapter, effort has been made to cite some of the earliest work which initiated the methods which have now become familiar.

13.1.2. Definition of noncrystallographic symmetry

13.1.2.1. Standard noncrystallographic symmetry

The standard cases of noncrystallographic symmetry arise when *there is more than one similar subunit in the crystallographic asymmetric unit*.

The phrase 'noncrystallographic symmetry' is used because the operation required to superimpose one subunit on another is similar to a symmetry operation, but it operates only over a local volume, and the symmetry is inexact because the subunits are in different environments.

The 'subunit' can be a molecular aggregate, a single molecule, a monomer unit of an oligomeric molecule, or a fragment of a molecule.

The word 'similar' is used because protein subunits in different environments are never identical. At the very least, surface side chains are differently ordered, and solvation is different because of different interactions with adjacent subunits.

If noncrystallographic symmetry exists, methods are available to define the operation required to superimpose one unit on another (Rossmann & Blow, 1962; Rossmann *et al.*, 1964). When this has been done, new information is available to improve the accuracy of structural results (Rossmann & Blow, 1963).

Table 13.1.2.1 presents different types of symmetry situations which may arise when noncrystallographic symmetry exists. It is frequently observed that the local symmetry corresponds or approximates to point-group symmetry. This arises very often because a natural molecular form is a symmetric oligomer whose symmetry is not fully expressed in the crystal symmetry [cases (1) and (3)]. Helical symmetry or pseudo-helical symmetry is also common [case (2)], especially in biological materials, but it cannot always be exploited crystallographically because the specimens are often noncrystalline fibres.

13.1.2.2. Generalized noncrystallographic symmetry

Crystallographic methods similar to those which exploit standard noncrystallographic symmetry can often be applied to a more general situation, where *similar subunits exist in different crystals* (Scouloudi, 1969; Tollin, 1969) *or where the structure of a subunit is already predictable* (Hoppe, 1957; Lattman & Love, 1970). The types of relationship which may arise are summarized in the right-hand column of Table 13.1.2.1.

13.1.2.3. Exploitation of noncrystallographic symmetry

In order to draw structural information from noncrystallographic symmetry, the different classes of subunit must provide different information. Cases of pseudo-crystallographic symmetry, where subunits are *almost* in an arrangement of higher crystallographic symmetry, are difficult to exploit by the techniques discussed in this chapter. Typically only weak reflections (those which would be forbidden by the higher symmetry if it were exact) provide extra information. This situation often arises in case (6), Table 13.1.2.1. Similarly in cases (7) and (8), comparison of crystals whose cell dimensions or contents are only slightly altered gives little new information.

13.1.3. Use of the Patterson function to interpret noncrystallographic symmetry

13.1.3.1. Rotation operations

The first step towards identifying and exploiting noncrystallographic symmetry is to find the operation that is required to superimpose one subunit upon another. Superposition of one

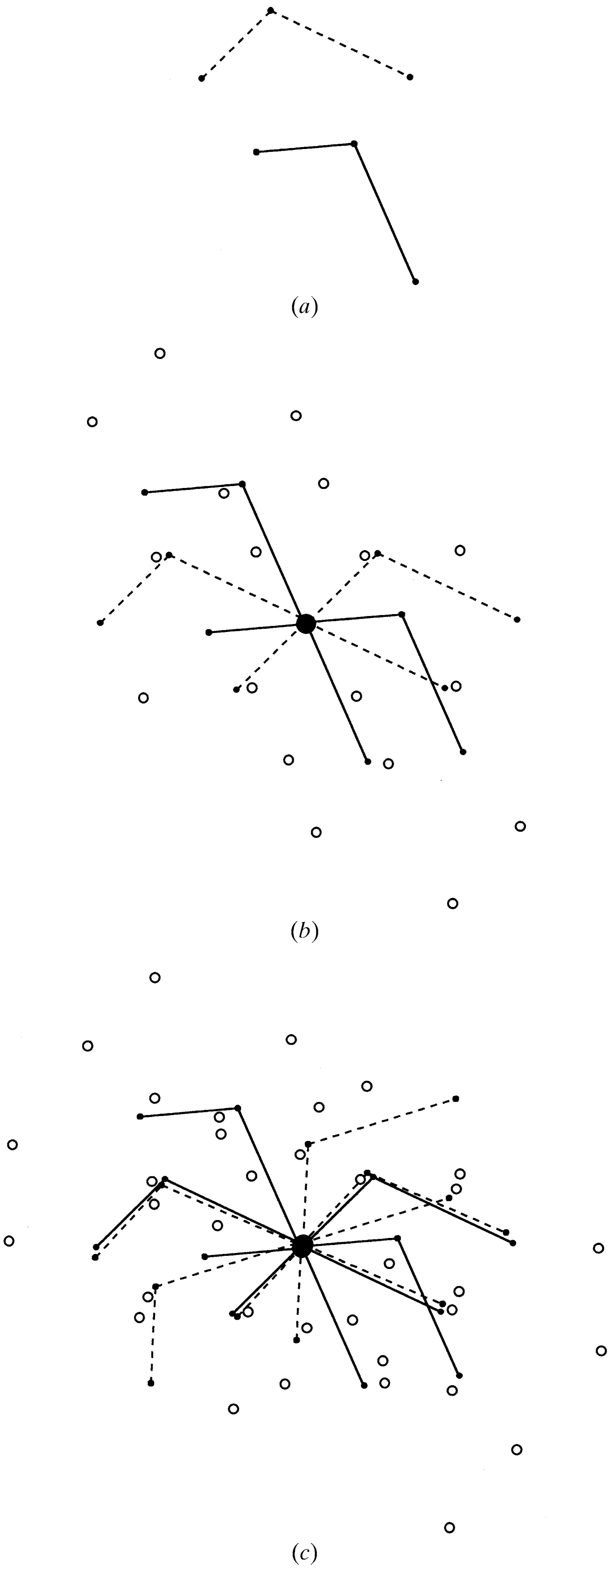

Figure 13.1.3.1
(*a*) A dimer in which the two subunits are related by arbitrary rotation and translation. One member of the dimer is indicated by dashed lines joining its atoms. (*b*) The vector set representing the Patterson function of this dimer. The intra-subunit vectors of each subunit are indicated by filled circles linked by lines; the inter-subunit vectors are shown as open circles. (*c*) A second copy of the Patterson function has been rotated over the original. Intra-subunit vectors of the original Patterson function are indicated by full lines; the rotated intra-subunit vectors are distinguished by dashed lines. The rotation is almost the same as the rotation of one subunit to make it parallel to the other. When the rotation is exactly correct, half of the intra-subunit vectors of one Patterson will superimpose onto the other. None of the inter-subunit vectors superimpose.

asymmetric rigid body upon a similar one requires in general that it be rotated and translated. A general rotation in three-dimensional space requires three variables to specify it: these can be the latitude and longitude of a rotation axis and the angle of rotation (κ, ψ, φ), or they can be the Euler angles. These rotational systems are presented in *IT* B (Rossmann & Arnold, 2001) and are discussed in detail in Chapter 13.2 by Navaza. Similarly, a general three-dimensional translation is specified by three variables. The operation to superimpose subunits therefore requires six variables to define it. Surveys or searches in six-dimensional functions are overwhelmingly laborious, though they have long been possible (Milledge, 1962; Kayushina & Vainshtein, 1965) and are now becoming easier (Kissinger *et al.*, 1999; Sheriff *et al.*, 1999).

The Patterson function, a function directly calculable from observed diffraction intensities, is a function which defines its own origin. Being a function in vector space, its origin is necessarily at a point representing a vector of zero length. It is this special property of the Patterson function which allows its use to factorize the six-dimensional problem into two three-dimensional ones. It is available without information about the phases of the diffraction data. Even when structural data are available, it is usually easier to make a three-dimensional rotation search based on the Patterson function than to carry out a full six-dimensional search using the known structure.

The Patterson function of a crystal may be considered to have two components: vectors between scattering centres in the same subunit, and those between different subunits. The intra-subunit vectors are necessarily shorter than the maximum subunit dimension. Inter-subunit vectors, though a few may be short, are clustered about the distances separating different subunits in the crystal, so they are mostly of the magnitude of the subunit dimensions or longer. By considering the region closer to the origin of the Patterson function, it is possible to include a high proportion of intra-subunit vectors.

Fig. 13.1.3.1 shows how the relation between the set of intra-subunit vectors of one subunit and the intra-subunit vectors of a similar subunit defines a rotation operation. This rotation is identical to the rotational part of the operation required to superimpose the subunits. If the whole Patterson function is rotated in this way, and then superimposed upon itself, one set of intermolecular vectors of the rotated Patterson function is superimposed upon a set of intermolecular vectors of the original (Fig. 13.1.3.1*c*). The self-rotation function (Rossmann & Blow, 1962) searches for correlations between a rotated Patterson function and the original.

By working with Patterson-function vectors, there is no dependence on the relative positions of the two subunits. Relative rotations can be determined in the standard case (Rossmann & Blow, 1962) or in the generalized case (Prothero & Rossmann, 1964; Lattman & Love, 1970). Methods for using the Patterson function to identify the rotation operation are detailed in Chapter 13.2.

13.1.3.2. Translation operations

When the rotation operation has been identified, the translation between the two differently oriented subunits needs to be determined (see Chapter 13.3 by Tong). The translation can only be defined in relation to an assigned origin of the subunit. It is possible to define the translation vector relative to the 'centres of gravity' (more precisely, the centres of scattering density) of the subunits. In this way, a translation may be defined between

Table 13.1.4.1
Structure determination using noncrystallographic symmetry

† Structure determinations of this kind have not been reported.

subunits of unknown structure. This approach, based only on information in the Patterson function, is the only available method if no phase information is available, but has several difficulties – it only applies accurately in certain cases, and the results are difficult to interpret and are imprecise (Blow *et al.*, 1964; Rossmann *et al.*, 1964). In practice, when dealing with a totally unknown structure, translational relationships are more frequently discovered by using specific markers on the subunit (intense scattering centres or 'heavy atoms', or anomalous scattering centres).

13.1.4. Interpretation of generalized noncrystallographic symmetry where the molecular structure is partially known

13.1.4.1. The cross-rotation function

The rotation function can be used in the generalized case to compare the Patterson functions of different crystals. When used in this way, it is called the cross-rotation function. In the most usual case, information providing some kind of structural model is available for one of the crystals.

The power of the cross-rotation function may be greatly improved by removing all intermolecular vectors from the 'model' Patterson function. This may be done by constructing an imaginary crystal structure in which a single copy of the structural model is placed in a unit cell that is large enough for all intermolecular vectors to be longer than the longest intramolecular vector of the model. In this cell, the self-Patterson vectors may be completely isolated and used for comparison with the Patterson function of a crystal containing a molecule of unknown orientation.

13.1.4.2. The cross-translation function

In searching for the position of a molecule in the generalized case of noncrystallographic symmetry, a molecular model defines an origin of coordinates in the model structure, and the corresponding position can be sought in an unknown structure (Nordman & Nakatsu, 1963; Tollin & Cochran, 1964; Huber, 1965; Crowther & Blow, 1967). The procedure is to calculate a three-dimensional function whose peaks should lie at the intersubunit vectors. In some procedures (Tollin & Cochran, 1964; Crowther & Blow, 1967), this function may be calculated as a Fourier series.

The translation functions will fail if the corresponding rotation is incorrect, or even if it is insufficiently accurate to give a good overlap between the structures. To avoid this danger, Brünger (1997) recommends computing translation functions using rotations corresponding to many (*e.g.* 200) high values of the rotation function. Though this is a huge increase in computing load, it still compares favourably with a full six-dimensional search.

These methods are considered further in Chapter 13.3.

13.1.4.3. Structure determination

Table 13.1.4.1 distinguishes a number of different situations in which noncrystallographic symmetry can be used to aid structure determination. The most frequent application of molecular-replacement methods is to cases where a structure is partially known, but is not yet susceptible to refinement by standard techniques.

Two types of situation arise in the standard case, where noncrystallographically related subunits exist in the same crystal. Most frequently [type (2)], the noncrystallographic symmetry allows the electron density to be improved at the given resolution. Occasionally, high-order noncrystallographic symmetry may be used to extend the resolution to the point where conventional structural refinement becomes possible (Schevitz *et al.*, 1981; McKenna *et al.*, 1992). In the most favourable case, high-order noncrystallographic symmetry constraints may allow direct structure determination [type (1)], starting from the position of a symmetric particle in the asymmetric unit (Jack, 1973).

In the generalized case, most often, similarities with a known molecular structure can be employed to improve an unknown structure [types (5) and (6)]. Such techniques were first used by Tollin (1969) (before structural refinement was possible) and by Fehlhammer & Bode (1975).

It is also possible that a refinable structure could be generated from intensity data observed from several different crystal forms, using noncrystallographic symmetry constraints, but this is not known to have been done in practice [types (3) and (4)].

13.1.5. The power of noncrystallographic symmetry in structure analysis

13.1.5.1. Relevant parameters: standard case

A poorly determined structure, if known at sufficient resolution and accuracy, can be improved by structural refinement of an atomic model to fit the observations. These methods often use existing structural knowledge (of bond lengths and angles, for example) to improve the convergence of the refinement process.

The most important contributions of noncrystallographic symmetry arise before this point of structure determination is reached. In this stage of structural analysis, the distribution of scattering density may be constrained by the requirements of noncrystallographic symmetry. The density may be improved by imposing noncrystallographic symmetry on poorly defined scattering density, and, in favourable cases, cyclical improvement leads to a unique corrected structure. To avoid any confusion with refinement of the atomic structure, this process will be referred to as 'symmetry correction' or 'correction' (Hoppe & Gassmann, 1968).

Noncrystallographic symmetry can also be used to improve the accuracy and convergence of atomic structural refinement by increasing the number of observations to a given resolution (Section 13.1.5.5).

The power of correction methods in improving an unknown structure in the standard case (Section 13.1.2.1) depends on:

(1) the resolution of the analysis, d;
(2) the number, N, of subunits per asymmetric unit;
(3) the volume fraction, NU/V_a, of the asymmetric unit over which the noncrystallographic symmetry operation applies;
(4) whether the density between subunit volumes is constant;
(5) the degree of similarity of the subunits being matched; and
(6) the extent to which the noncrystallographic symmetry operations differ from the crystal symmetry operations.

The first three parameters are expressed in quantitative terms; parameter (4) might be true or false, but more often lies between these; and parameters (5) and (6) are not easily expressed in measurable form.

The resolution d should ideally be matched to the level of similarity of the subunits. The root-mean-square displacement between an atom in one subunit and the rotated and translated position of the corresponding atom from another subunit (or model subunit) provides an order of magnitude for the resolution d which can be used effectively. In many cases, the resolution is worse than this for practical reasons of crystal disorder and data collection.

This limit was encountered by Huber *et al.* (1974) working at 1.9 Å resolution. They found that a model structure with a mean coordinate difference of 1.9 Å was not usable for molecular replacement, while another model agreeing to 0.75 Å gave results which allowed the structure to be refined. This suggests that agreement significantly better than the resolution is required.

13.1.5.2. Information gain from ideal noncrystallographic symmetry

Rossmann & Blow (1962) wrote, "The effect of noncrystallographic symmetry ... results in decreasing the size of the structure to be determined, while the number of observable intensities remains the same. This 'redundancy' in information might be used to help solve a structure." This idea is developed below.

First, it will be shown that (in the absence of noncrystallographic symmetry) there is a constant ratio between the number of independent measurements required to specify the scattering density at a chosen resolution and the volume of the asymmetric unit. Then the effect of noncrystallographic symmetry on this ratio is discussed. The importance of the ratio (volume of symmetry-constrained unit/volume of asymmetric unit) ($= U/V_a$) is stressed. Another ratio is developed – available no. of measurements/ideally required no. of measurements – and this is referred to as the overdetermination ratio.

Consider a noncentrosymmetric crystal whose asymmetric unit volume is V_a and whose diffraction data have been measured to a resolution d. If the multiplicity of the space group (number of asymmetric units in the primitive unit cell) is Z, the volume of reciprocal space, V^*, per point of the primitive reciprocal lattice is given by

$$V^* = 1/V = 1/ZV_a,$$

where V is the volume of the primitive unit cell.

The number of independent orders of diffraction (the number of independent intensities) within the resolution sphere of radius $1/d$ is given by

$$N_{\rm ref} = \left(\frac{4\pi}{3d^3}\right)\left(\frac{1}{V^*}\right)\left(\frac{1}{2Z}\right) = \frac{2\pi V_a}{3d^3}. \qquad (13.1.5.1)$$

In this formula, Friedel's law is supposed to apply. A set of $2Z$ reflections have identical intensity due to the combined effects of Friedel's law and crystal symmetry. When $N_{\rm ref}$ is expressed in terms of V_a, the multiplicity factor disappears.

To calculate the scattering density over the volume V_a at resolution d, $2N_{\rm ref}$ independent quantities need to be specified (say, the real and imaginary parts of each of the $N_{\rm ref}$ independent structure factors). The required number of measurements is

$$R = 2N_{\rm ref} = (4\pi/3d^3)V_a. \qquad (13.1.5.2)$$

If only the diffracted intensities can be measured, they provide exactly half the $2N_{\rm ref}$ measurements required to calculate the density at resolution d.

In what follows, it is assumed that the required number of measurements, R, to specify the scattering density at the chosen resolution is proportional to the volume over which the density must be specified. This is true when the volume is a crystallographic asymmetric unit [equation (13.1.5.2)], and it agrees with another analysis discussed below. Following this argument, the overdetermination ratio

$$\frac{\text{available no. of measurements}}{\text{ideally required no. of measurements}} = \frac{N_{\rm ref}}{R} = \frac{V_a}{2X}, \quad (13.1.5.3)$$

where X is the volume whose density is unknown.

Next, consider that ideal noncrystallographic symmetry applies. The crystal asymmetric unit contains N identical subunits and no other scattering matter. Since the symmetry is noncrystallographic, it is never possible to fit the subunit volumes together so as to fill the unit cell exactly. The volume assigned to each subunit, U, has to be less than V_a/N, leaving some parts of the unit cell not assigned to any subunit. In the case of ideal noncrystallographic symmetry, these regions are necessarily empty. In this case $X = U$, which is less than V_a/N, so from equation (13.1.5.3)

$$\text{overdetermination ratio} = (V_a/2U) > N/2.$$

Even where N is only 2, more intensity data are available than the number of measurements ideally required to specify the electron density at resolution d.

A more sophisticated analysis of the number of variables required to define a structure with noncrystallographic symmetry has been made in terms of sets of orthogonal 'eigendensity functions', which satisfy the noncrystallographic symmetry (Crowther, 1967). Any structure satisfying the symmetry requirements can be constructed from the appropriate set of eigendensities. Crowther (1969) demonstrated that the number of eigendensities m is approximately $(2N_{\rm ref}U/V_a)$.

The structure is specified by m weights, which are applied to the m allowed eigendensities (which depend only on the symmetry constraints), so the overdetermination ratio

$$\frac{\text{available no. of measurements}}{\text{ideally required no. of measurements}} = \frac{N_{\rm ref}}{m} = \frac{V_a}{2U},$$

the same result as before, showing that the two methods of analysis approximately agree.

13.1.5.3. *Information gain in the non-ideal case*

In the non-ideal case, the definition of volume U assigned to each subunit assumes an important role. It is particularly important that the volumes should not overlap, since this may set up a chain of unrealizable constraints. In imposing noncrystallographic symmetry, the volumes between subunits are often unconstrained, allowing for differences in solvent structure and surface side chains following from their different environments. In addition to the volume U of one subunit, whose structure is to be defined, an additional volume, $V_a - NU$, is left unconstrained. The volume X of unknown electron density is $U + (V_a - NU)$, and, using equation (13.1.5.3), the overdetermination ratio

$$\frac{\text{available no. of measurements}}{\text{ideally required no. of measurements}} = \frac{V_a}{2[V_a - (N-1)U]}. \qquad (13.1.5.4)$$

If $N = 2$, U must be less than $V_a/2$, and the overdetermination ratio in equation (13.1.5.4) must be less than 1, so in the non-ideal case there is no chance of convergent correction. This confirms the practical observation that although averaging electron density with $N = 2$ can improve the structure (Matthews *et al.*, 1967), it does not lead to convergent correction (B. W. Matthews, unpublished results). Slowly convergent *ab initio* structure correction was reported at 6.3 Å resolution for $N = 4$ (Argos *et al.*, 1975). In this case, the volume $4U$ of the constrained tetramer was reported to be only about $V_a/2$. Substituting $N = 4$, $U = V_a/8$ in the above expression gives an overdetermination ratio of only 1.6, which was sufficient to allow convergent correction.

An alternative possibility is to constrain the density between subunits to a constant value, even when this may not be precisely correct, in order to improve the convergence of symmetry correction. There is a close analogy to solvent-flattening techniques used in density modification and atomic structural refinement (Schevitz *et al.*, 1981; Wang, 1985). The volume constrained to a constant value is now $V_a - NU$. The volume whose structure is to be determined is only U, and in place of equation (13.1.5.4),

$$\frac{\text{available no. of measurements}}{\text{ideally required no. of measurements}} = \frac{V_a}{2U},$$

as in the ideal case. Such a constraint, while only approximately valid, may allow structure correction to proceed convergently, as found by Rossmann *et al.* (1992). The constraint may be released at a later stage.

This analysis also emphasizes the importance of specifying the size and shape of the subunit volume U as closely as possible (Wilson *et al.*, 1981). Methods of automatic refinement of the chosen volume are available (Rossmann *et al.*, 1992; Abrahams & Leslie, 1996).

13.1.5.4. *Relevant parameters: generalized case*

In the generalized case it is obvious that noncrystallographic symmetry makes more measurements available, since the data from more than one type of crystal are being used. The volume of the subunit U must be less than V_a in each type of crystal. Making a simple assumption of two crystals, each with one subunit in each asymmetric unit, the available number of measurements per volume of the subunit is, in the ideal case,

$$\frac{N_{\rm ref1} + N_{\rm ref2}}{U} = \left(\frac{2\pi}{3d^3}\right)\left(\frac{V_{a1} + V_{a2}}{U}\right) > 2\left(\frac{2\pi}{3d^3}\right).$$

Thus, the overdetermination ratio $= (N_{\rm ref1} + N_{\rm ref2})/(4\pi U/3d^3) > 1$, so even in this case the structure is theoretically overdetermined.

This type of reasoning can be applied to analysis of a crystal which includes a unit of known structure and also another unit whose structure is unknown [type (6), Table 13.1.4.1]. A complex between an enzyme of known structure with an unknown inhibitor provides a familiar example. Note first that the envelope defining the volume U of known structure must be tightly defined, since otherwise unwanted features will be taken over into the unknown structure.

If this known structure of volume U appears once in the asymmetric unit V_a of the partly unknown structure, can noncrystallographic symmetry correction be used to define a unique structure at resolution d?

The unconstrained volume is $V_a - U$. The number of measurements required to define this density at the given resolution is $4\pi(V_a - U)/3d^3$. The partially unknown structure provides $2\pi V_a/3d^3$ measured intensities to this resolution, and specification of the contents of U at resolution d is equivalent to $4\pi U/3d^3$ measurements. Thus the overdetermination ratio is

$$\frac{(2\pi V_a/3d^3) + (4\pi U/3d^3)}{4\pi(V_a - U)/3d^3} = \frac{V_a + 2U}{2(V_a - U)}.$$

The overdetermination ratio is greater than 1 if $U > V_a/4$, that is, if only a quarter of the asymmetric unit represents known structure. Although this relationship applies to an 'ideal' case and is therefore certainly too optimistic, it indicates the remarkable power of the molecular-replacement method. If, for example, half the unit cell is devoted to unknown structure ($U = V_a/2$), the overdetermination ratio is ideally 2.

13.1.5.5. *Noncrystallographic symmetry in atomic coordinate refinement*

In atomic coordinate refinement, noncrystallographic symmetry again provides a useful increase in the ratio of the number of observed quantities to the number of atomic parameters to be refined. As is discussed by Cruickshank in Chapter 18.5, the application of restraints in refinement (on quantities like bond lengths, bond angles and the elimination of short contacts) is formally equivalent to an increase in the number of observational equations. However, if these restraints are tightly applied, they act more like constraints, and their effect is more like a reduction in the number of parameters to be determined. Meaningful refinement is not possible unless the number of observations exceeds the number of parameters, and in practice it usually needs to do so by a factor of 2 or so. If noncrystallographic symmetry is imposed, the number of observations required to define the structure is reduced, because the volume of unknown structure is reduced.

Noncrystallographic symmetry can thus provide a crucial advantage in leading to unambiguous interpretation of structure at relatively poor resolution (say, 3.0 to 3.8 Å), where the ratio of refined parameters to the number of observations is marginal. Consider two crystals of the same material, one of which has one subunit per asymmetric unit and the asymmetric volume is V_1. The other has N subunits in an asymmetric unit of volume V_N. To the same resolution, the available number of observed reflections is increased in the ratio V_N/V_1, in order to obtain the same number of parameters if noncrystallographic symmetry is imposed.

What effect do these N subunits have on the precision of the final coordinates? The crystal allows the determination of N sets of atomic coordinates. If the errors were independent of each other, the precision of the mean value of each coordinate could be improved in the ratio $N^{-1/2}$ (compared to a well refined V_1 structure).

This improvement will be lost when constraints are applied to the mean coordinates (to make them conform to given bond lengths and angles, for example). If this is done, the errors are no longer independent, and the increase of precision will be less.

Cruickshank (1999*a*,*b* and Chapter 18.5) shows that at high resolution (examples at 0.94 and 1.0 Å) and for atoms of low B factor (less than say 10 Å^2), restraints make little difference to the precision of refinement. Under these conditions, N independent subunits in the asymmetric unit might improve the precision of the mean coordinates by a factor approaching $N^{-1/2}$. But at such good resolution, it is very possible that the differences between the calculated subunit conformations are not due to error, but reflect real structural differences. If so, the precision of the mean coordinates is less significant.

At less high resolution (example given at 1.7 Å), Cruickshank has shown that the precision of unrestrained refinement is significantly worse than the precision of the restraints. In this case, imposing noncrystallographic symmetry on the structure should provide some improvement. But because the coordinate errors then cease to be independent, the improvement in the mean coordinates would be less.

Chapter 13.2. Rotation functions

J. Navaza

13.2.1. Overview

We will discuss a technique to find either the relative orientations of homologous but independent subunits connected by noncrystallographic symmetry (NCS) elements or the absolute orientations of these subunits if the structure of a similar molecule or fragment is available. The procedure makes intensive use of properties of the rotation group, so we will start by recalling some properties of rotations. More advanced results are included in Appendix 13.2.1.

13.2.2. Rotations in three-dimensional Euclidean space

A rotation **R** is specified by an oriented axis, characterized by the unit vector **u**, and the spin, χ, about it. Positive spins are defined by the right-hand screw sense and values are given in degrees. An almost one-to-one correspondence between rotations and parameters $(\chi, \mathbf{u})$ can be established. If we restrict the spin values to the positive interval $0 \leq \chi \leq 180$, then for each rotation there is a unique vector $\chi\mathbf{u}$ within the sphere of radius 180. However, vectors situated at opposite points on the surface correspond to the same rotation, *e.g.* $(180, \mathbf{u})$ and $(180, -\mathbf{u})$.

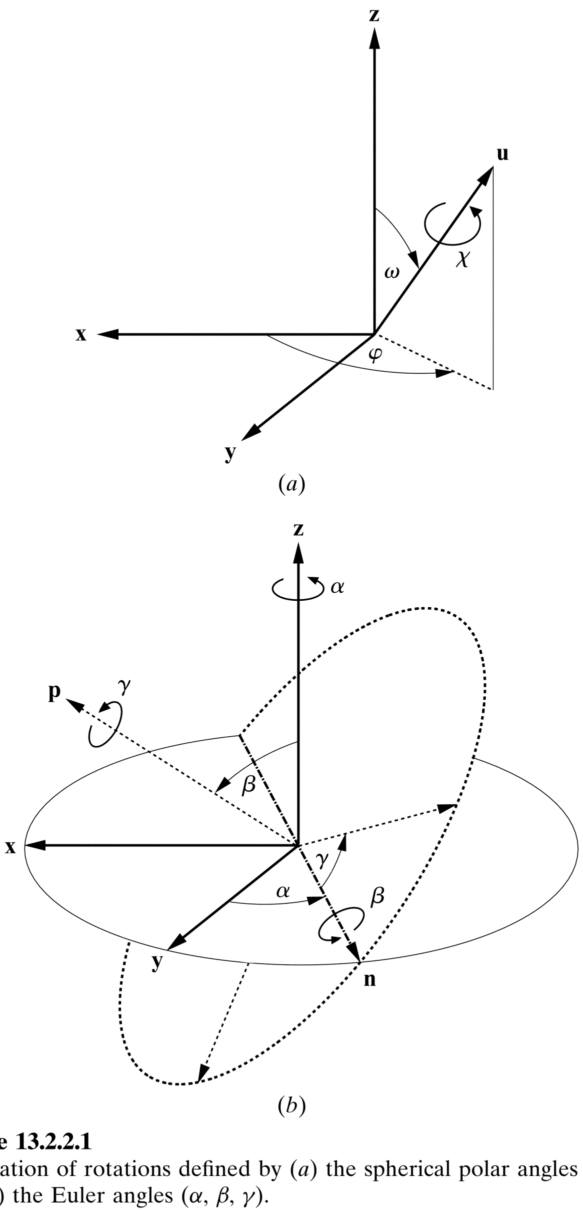

Figure 13.2.2.1
Illustration of rotations defined by (*a*) the spherical polar angles (χ, ω, φ); (*b*) the Euler angles (α, β, γ).

When the unit vector **u** is specified by the colatitude ω and the longitude φ with respect to an orthonormal reference frame (see Fig. 13.2.2.1*a*), we have the spherical polar parameterization of rotations (χ, ω, φ). The range of variation of the parameters is

$$0 \leq \chi \leq 180;\ \ 0 \leq \omega \leq 180;\ \ 0 \leq \varphi < 360.$$

Rotations may also be parameterized with the Euler angles (α, β, γ) associated with an orthonormal frame $(\mathbf{x}, \mathbf{y}, \mathbf{z})$. Several conventions exist for the names of angles and definitions of the axes involved in this parameterization. We will follow the convention by which (α, β, γ) denotes a rotation of α about the z axis, followed by a rotation of β about the nodal line n, the rotated y axis, and finally a rotation of γ about **p**, the rotated z axis (see Fig. 13.2.2.1*b*):

$$\mathbf{R}(\alpha, \beta, \gamma) = \mathbf{R}(\gamma, \mathbf{p})\mathbf{R}(\beta, \mathbf{n})\mathbf{R}(\alpha, \mathbf{z}). \tag{13.2.2.1}$$

The same rotation may be written in terms of rotations around the fixed orthonormal axes. By using the group property

$$\mathbf{T}\mathbf{R}(\chi, \mathbf{u})\mathbf{T}^{-1} = \mathbf{R}(\chi, \mathbf{T}\mathbf{u}), \tag{13.2.2.2}$$

which is valid for any rotation **T**, we obtain (see Appendix 13.2.1)

$$\mathbf{R}(\alpha, \beta, \gamma) = \mathbf{R}(\alpha, \mathbf{z})\mathbf{R}(\beta, \mathbf{y})\mathbf{R}(\gamma, \mathbf{z}). \tag{13.2.2.3}$$

The parameters (α, β, γ) take values within the parallelepiped

$$0 \leq \alpha < 360;\ \ 0 \leq \beta \leq 180;\ \ 0 \leq \gamma < 360.$$

Here again, different values of the parameters may correspond to the same rotation, *e.g.* $(\alpha, 180, \gamma)$ and $(\alpha - \gamma, 180, 0)$.

Although rotations are abstract objects, there is a one-to-one correspondence with the orthogonal matrices in three-dimensional space. In the following sections, **R** will denote a 3×3 orthogonal matrix. An explicit expression for the matrix which corresponds to the rotation $(\chi, \mathbf{u})$ is

$$\begin{bmatrix} \cos\chi + u_1u_1(1-\cos\chi) & u_1u_2(1-\cos\chi) - u_3\sin\chi & u_1u_3(1-\cos\chi) + u_2\sin\chi \\ u_2u_1(1-\cos\chi) + u_3\sin\chi & \cos\chi + u_2u_2(1-\cos\chi) & u_2u_3(1-\cos\chi) - u_1\sin\chi \\ u_3u_1(1-\cos\chi) - u_2\sin\chi & u_3u_2(1-\cos\chi) + u_1\sin\chi & \cos\chi + u_3u_3(1-\cos\chi) \end{bmatrix} \tag{13.2.2.4}$$

or, in condensed form,

$$\mathbf{R}(\chi, \mathbf{u})_{ij} = \delta_{ij}\cos\chi + u_iu_j(1-\cos\chi) + \sum_{k=1}^{3}\varepsilon_{ikj}u_k\sin\chi, \tag{13.2.2.5}$$

where δ_{ij} is the Kronecker tensor, u_i are the components of **u**, and ε_{ijk} is the Levi–Civita tensor. The rotation matrix in the Euler parameterization is obtained by substituting the matrices in the right-hand side of equation (13.2.2.3) by the corresponding expressions given by equation (13.2.2.4).

13.2.2.1. The metric of the rotation group

The idea of distance between rotations is necessary for a correct formulation of the problem of sampling and for plotting functions of rotations (Burdina, 1971; Lattman, 1972). It can be demonstrated that the quantity

$$\mathrm{d}s^2 = \mathrm{Tr}\big(\mathrm{d}\mathbf{R}\ \mathrm{d}\mathbf{R}^{+}\big) = \sum_{i,j=1}^{3} (\mathrm{d}R_{ij})^2 \qquad (13.2.2.6)$$

defines a metric on the rotation group, unique up to a multiplicative constant, which cannot be reduced to a Cartesian metric. This is a topological property of the group, independent of its parameterization. ds is interpreted as the distance between the rotations $\mathbf{R}$ and $\mathbf{R} + \mathrm{d}\mathbf{R}$. With the Euler parameterization, equation (13.2.2.6) becomes

$$\mathrm{d}s^2 = \mathrm{d}\alpha^2 + 2\cos(\beta)\ \mathrm{d}\alpha\ \mathrm{d}\gamma + \mathrm{d}\gamma^2 + \mathrm{d}\beta^2. \qquad (13.2.2.7)$$

The volume element of integration, $\sin(\beta)\ \mathrm{d}\alpha\ \mathrm{d}\beta\ \mathrm{d}\gamma$, corresponding to this length element guarantees the invariance of integrals over the rotation angles with respect to initial reference orientations.

The distance defined by equation (13.2.2.6) has a simple physical interpretation. Let us consider a molecule with initial atomic coordinates $\{\mathbf{x}\}$, referred to an orthonormal frame parallel to the molecule's principal moments of inertia, I_i. Then, the coordinates satisfy the conditions

$$\begin{aligned} \langle x_i\ x_j\rangle &= 0 \quad \text{if } i \neq j,\\ \langle x_i\ x_i\rangle &= I_i, \end{aligned} \qquad (13.2.2.8)$$

where $\langle \ldots \rangle$ means 'average over atoms'. If we move the molecule from a rotated position characterized by the rotation $\mathbf{R}$ to a close one characterized by $\mathbf{R} + \mathrm{d}\mathbf{R}$, the mean-square shift of the atomic coordinates is

$$\sigma^2 = \langle (\mathrm{d}\mathbf{R}\ \mathbf{x})^2\rangle = \sum_{i=1}^{3} I_i \sum_{j=1}^{3} (\mathrm{d}R_{ij})^2. \qquad (13.2.2.9)$$

When all the I_i are equal, σ becomes proportional to ds.

13.2.3. The rotation function

The absolute and relative orientations of the subunits that constitute a crystal may in principle be found by exploiting some properties of the Patterson function. We first express the crystal structure factors $F(\mathbf{h})$ in terms of the Fourier transform of the electron density of isolated molecules, $f_m(\mathbf{s})$, calculated with their centres of gravity placed at the origin. If $\mathbf{r}_m$ denotes the position within the crystal of the centre of gravity of the mth molecule, we have

$$F(\mathbf{h}) = \sum_{m=1}^{M} f_m(\mathbf{h}) \exp(2\pi i \mathbf{h}\mathbf{r}_m), \qquad (13.2.3.1)$$

where M is the number of molecules within the unit cell. This is a general expression for $F(\mathbf{h})$, although the space-group and noncrystallographic rotational symmetries are not explicitly exhibited. The presence of symmetry implies that some of the $f_m(\mathbf{h})$'s are in fact samples of the same function at rotated arguments. The Fourier coefficients of the Patterson function can then be written as

$$\begin{aligned} I(\mathbf{h}) = |F(\mathbf{h})|^2 &= \sum_{m=1}^{M} |f_m(\mathbf{h})|^2 \\ &+ \sum_{m\neq m'=1}^{M} \overline{f_m(\mathbf{h})}\, f_{m'}(\mathbf{h}) \exp[2\pi i \mathbf{h}(\mathbf{r}_m - \mathbf{r}_{m'})], \end{aligned} \qquad (13.2.3.2)$$

where $\overline{f_m}$ is the complex conjugate of f_m. The first term in equation (13.2.3.2) involves only intramolecular contributions or self-Patterson terms; they are centred at the origin of the Patterson function. The second term involves intermolecular contributions or cross-Patterson terms; they are centred at the intermolecular vectors $\mathbf{r}_m - \mathbf{r}_{m'}$. Therefore, if we restrict the Patterson function to a region Ω, of volume v, centred at the origin and having a dimension of the order of the dimensions of the isolated molecules, self-Patterson terms will dominate the crossed ones.

Thus it becomes possible to determine the rotation $\mathbf{R}$ that superimposes one subunit upon an independent, homologous one by calculating the overlap within the region Ω of the observed Patterson function (the target function P_t) and a rotated version of either itself or the Patterson function of an isolated known molecule (the search function P_s):

$$\mathcal{R}(\mathbf{R}) = (1/v) \int_{\Omega} P_t(\mathbf{r}) P_s(\mathbf{R}^{-1}\mathbf{r})\ \mathrm{d}^3\mathbf{r} \qquad (13.2.3.3)$$

(Rossmann & Blow, 1962). $\mathcal{R}$ should display a local maximum for the sought rotation. Note that when we rotate the search function P_s by $\mathbf{R}$, its argument contains $\mathbf{R}^{-1}$. When the search and the target functions are the same, $\mathcal{R}$ is called the self-rotation function; otherwise, it is called the cross-rotation function. When a model is available, the target data are calculated by placing the model within a $P1$ cell whose dimensions guarantee that Ω only contains self-Patterson contributions.

The reciprocal-space formulation of the above integral is obtained by substituting the Patterson functions by their Fourier summations:

$$P(\mathbf{r}) = \sum_{\mathbf{h}} [I(\mathbf{h})/V] \exp(-2\pi i \mathbf{h}\mathbf{r}). \qquad (13.2.3.4)$$

Taking into account that $I(-\mathbf{h}) = I(\mathbf{h})$, we obtain

$$\begin{aligned} \mathcal{R}(\mathbf{R}) &= \sum_{\mathbf{h}}\sum_{\mathbf{k}} \frac{I_t(\mathbf{h})}{V_t}\frac{I_s(\mathbf{k})}{V_s}\frac{1}{v}\int_{\Omega} \exp[2\pi i(\mathbf{h} - \mathbf{k}\mathbf{R}^{-1})\mathbf{r}]\ \mathrm{d}^3\mathbf{r} \\ &= \sum_{\mathbf{h}}\sum_{\mathbf{k}} \frac{I_t(\mathbf{h})}{V_t}\frac{I_s(\mathbf{k})}{V_s}\ \chi_{\Omega}(\mathbf{h} - \mathbf{k}\mathbf{R}^{-1}). \end{aligned} \qquad (13.2.3.5)$$

χ_{Ω}, the interference function, is the Fourier transform of the characteristic function of Ω, *i.e.*, a function that takes the value 1 within Ω and 0 outside. In principle, the domain of integration could have any shape. However, in order to take full advantage of the properties of the rotation group, Ω is usually chosen as a spherical domain of radius b. Calling $\mathbf{h} - \mathbf{k}\mathbf{R}^{-1} = \mathbf{s}$ for short, we have

$$\begin{aligned} \chi_b(\mathbf{s}) &= (3/4\pi b^3) \int_0^b\int_0^{\pi}\int_0^{2\pi} \exp(2\pi i \mathbf{s}\mathbf{r}) r^2 \sin(\theta)\ \mathrm{d}r\ \mathrm{d}\theta\ \mathrm{d}\varphi \\ &= 3[\sin(2\pi sb) - 2\pi sb\cos(2\pi sb)]\big/(2\pi sb)^3. \end{aligned} \qquad (13.2.3.6)$$

In the case of a spherical shell with inner and outer radii a and b, respectively, the interference function is obtained by subtraction:

$$[\chi_b(\mathbf{s}) - (a/b)^3 \chi_a(\mathbf{s})]\big/[1 - (a/b)^3]. \qquad (13.2.3.7)$$

Although simple, the resulting expression for the rotation function has the disadvantage of containing entangled $\mathbf{h}$, $\mathbf{k}$ and $\mathbf{R}$ contributions, which renders its computation time-consuming if the whole domain of rotations has to be explored. The difficulty may be overcome by expanding the exponentials entering equation (13.2.3.5) in spherical harmonics, $Y_{\ell,m}$. Taking advantage of their transformation under rotations, and using recurrence relationships between spherical Bessel functions, j_{ℓ}, we obtain (see Appendix 13.2.1)

$$\chi_b(\mathbf{h}-\mathbf{k}\mathbf{R}^{-1}) = \sum_{\ell=0}^{\infty}\sum_{m,\,m'=-\ell}^{\ell} \overline{Y_{\ell,\,m}(\hat{\mathbf{h}})}\; Y_{\ell,\,m'}(\hat{\mathbf{k}}) \times \left\{\sum_{n=1}^{\infty} 12\pi[2(\ell+2n)-1]\,\frac{j_{\ell+2n-1}(2\pi hb)}{2\pi hb}\,\frac{j_{\ell+2n-1}(2\pi kb)}{2\pi kb}\right\} \times D^{\ell}_{m,\,m'}(\mathbf{R}), \tag{13.2.3.8}$$

where $D^{\ell}_{m,\,m'}$ are the matrices of the irreducible representations of the rotation group and $\hat{\mathbf{h}}$ stands for 'angular part of vector $\mathbf{h}$'. The awkwardness of equation (13.2.3.8) is apparent rather than real. Indeed:

(1) The expression separates angular from crystal variables. It also separates target from search contributions (see Section 13.2.3.1).

(2) The equation is accurate, even when truncating the summations on ℓ and n to reasonable values (Navaza, 1993). The upper limit for ℓ is of the order of the highest argument of the spherical Bessel functions,

$$\ell_{\max} \simeq 2\pi b/d_{\min},$$

where $d_{\min}$ is the resolution of the data. The upper limit for n also depends on the current value of ℓ,

$$n_{\max}(\ell) \simeq (\ell_{\max} - \ell + 2)/2.$$

(3) When the rotations are parameterized in Euler angles (α, β, γ), the matrices $D^{\ell}_{m,\,m'}$ take the form

$$D^{\ell}_{m,\,m'}(\alpha,\beta,\gamma) = d^{\ell}_{m,\,m'}(\beta)\exp[i(m\alpha + m'\gamma)], \tag{13.2.3.9}$$

which enables the computation of $\mathcal{R}$, for each given value of β, by means of two-dimensional fast Fourier transforms (FFTs).

This formulation is referred to as the fast rotation function (Crowther, 1972).

It may be useful to compare rotation functions obtained under different conditions. For this, some kind of normalization is needed. One possibility is to cast $\mathcal{R}$ into the form of a correlation coefficient by dividing equation (13.2.3.3) by the norms of the truncated Patterson functions,

$$\mathcal{R}_N(\mathbf{R}) = \int_{\Omega} P_t(\mathbf{r})P_s(\mathbf{R}^{-1}\mathbf{r})\,\mathrm{d}^3\mathbf{r} \bigg/ \left[\int_{\Omega} P_t(\mathbf{r})^2\,\mathrm{d}^3\mathbf{r} \int_{\Omega} P_s(\mathbf{r})^2\,\mathrm{d}^3\mathbf{r}\right]^{1/2}. \tag{13.2.3.10}$$

13.2.3.1. *Computing the rotation function*

A direct evaluation of equation (13.2.3.3) is possible. However, since the values of the Patterson functions are only available at discrete sampling points, an interpolation is needed after each rotation. This method is known as the direct-space formulation of the rotation function (Nordman, 1966; Steigemann, 1974).

In the reciprocal-space formulation [equations (13.2.3.5) and (13.2.3.6)], some precautions are to be taken in order to save computing time:

(1) Use only strong reflections in the summations.

(2) For each $\mathbf{k}\mathbf{R}^{-1}$, limit the summation on $\mathbf{h}$ to vectors satisfying the condition $|\mathbf{h} - \mathbf{k}\mathbf{R}^{-1}| \leq 1/2\pi b$.

In both formulations, it is worth using a distance between rotations to sample $\mathcal{R}$ efficiently, as explained in Section 13.2.3.2.

For the fast rotation function [equations (13.2.3.5) and (13.2.3.8)], the calculations are organized as follows (Dodson, 1985; Navaza, 1993):

(1) Given the search and the target diffraction data, compute

$$e_{\ell,\,m,\,n} = \left\{12\pi[2(\ell+2n)-1]\right\}^{1/2} \times \sum_{\mathbf{h}} [I(\mathbf{h})/V]\,Y_{\ell,\,m}(\hat{\mathbf{h}})[j_{\ell+2n-1}(2\pi hb)]/2\pi hb \tag{13.2.3.11}$$

and normalize [to compute equation (13.2.3.10)]:

$$e_{\ell,\,m,\,n} \rightarrow e_{\ell,\,m,\,n} \bigg/ \left(\sum_{\ell=2}^{\ell_{\max}} \sum_{m=-\ell}^{\ell} \sum_{n=1}^{n_{\max}(\ell)} |e_{\ell,\,m,\,n}|^2\right)^{1/2}. \tag{13.2.3.12}$$

Odd ℓ terms disappear, because the Friedel-related reflections contribute with opposite signs:

$$I(-\mathbf{h})Y_{\ell,\,m}(-\hat{\mathbf{h}}) = (-1)^{\ell} I(\mathbf{h})Y_{\ell,\,m}(\hat{\mathbf{h}}).$$

Also, if the Patterson function has an n-fold rotation axis along $\mathbf{z}$, only the terms with m equal to a multiple of n survive.

(2) Given the $e_{\ell,\,m,\,n}$'s, perform the sums

$$C^{\ell}_{m,\,m'} = \sum_{n=1}^{n_{\max}(\ell)} \overline{e^{(t)}_{\ell,\,m,\,n}}\; e^{(s)}_{\ell,\,m',\,n}. \tag{13.2.3.13}$$

(3) For each β value, calculate the reduced matrix elements and compute

$$S_{m,\,m'}(\beta) = \sum_{\ell=2}^{\ell_{\max}} C^{\ell}_{m,\,m'} d^{\ell}_{m,\,m'}(\beta). \tag{13.2.3.14}$$

Then evaluate the β section of $\mathcal{R}$ by FFT:

$$\mathcal{R}(\alpha,\beta,\gamma) = \sum_{m,\,m'=-\ell_{\max}}^{\ell_{\max}} S_{m,\,m'}(\beta)\exp[i(m\alpha + m'\gamma)]. \tag{13.2.3.15}$$

The sampling in α and γ here is dictated by the standard FFT requirements.

13.2.3.2. *Plotting and sampling the rotation function*

An odd feature of the rotation domain is that quite different values of the parameters may correspond to very close rotations. This causes the graphic representation of the rotation function to be distorted. For example, when the Euler angle β is small or close to 180, a peak plotted on a Cartesian grid in α and γ is strongly elongated in one direction. By redefining the reference orientation, the same peak near the $\beta = 90$ section will have a quite different – natural – shape.

This problem may be partially overcome by using the distance between rotations introduced in Section 13.2.2.1. Although the metric cannot be reduced to a Cartesian one in three dimensions, it is possible to do so for two-dimensional sections. Indeed, for fixed β, the transformation

$$\begin{aligned} \omega_+ &= \cos(\beta/2)(\alpha+\gamma) \\ \omega_- &= \sin(\beta/2)(\alpha-\gamma) \end{aligned} \tag{13.2.3.16}$$

reduces equation (13.2.2.7) to $\mathrm{d}s^2 = \mathrm{d}\omega_+^2 + \mathrm{d}\omega_-^2$. Therefore, distortion-free β sections may be plotted in terms of the variables $\omega_{\pm}$ (Burdina, 1971; Lattman, 1972). Accordingly, a correct sampling of $\mathcal{R}$ should consist of points regularly spaced in these variables. The number of points with respect to that of a regular spacing in α, β and γ is approximately

$$\int \sin(\beta)\,\mathrm{d}\alpha\,\mathrm{d}\beta\,\mathrm{d}\gamma \Big/ \int \mathrm{d}\alpha\,\mathrm{d}\beta\,\mathrm{d}\gamma = 2/\pi \simeq 0.64.$$

Notice that for β equal to 0 or 180, the sections reduce to lines.

In the case of the self-rotation function, when the order of the NCS may be anticipated, it is worth working with equation (13.2.2.6) in the polar parameterization,

$$\mathrm{d}s^2 = \mathrm{d}\chi^2 + [2\sin(\chi/2)]^2\mathrm{d}\mathbf{u}^2. \qquad (13.2.3.17)$$

For constant χ, we have the topology of the spherical surface. It is then natural to plot the function as a stereographic projection.

In the case of the cross-rotation function, *i.e.*, when the atomic distribution of the search model is known, we may use equation (13.2.2.9) instead of equation (13.2.2.6) to define the sampling. For this, we choose σ as the smallest root-mean-square shift in atomic coordinates that produces an appreciable change in the value of the cross-rotation function. An acceptable sampling set of $\mathcal{R}$ should then satisfy the following conditions:

(1) For every point in the rotation domain, there is at least one sampling point at a distance less than σ.
(2) The number of sampling points is as small as possible.

13.2.3.3. Strategies

Since the first attempts to detect subunits within the crystal asymmetric unit, a great deal of experience has been gained and the results collected in several treatises on molecular replacement (Rossmann, 1972; Machin, 1985; Dodson *et al.*, 1992; Carter & Sweet, 1997).

The success of the rotation function relies in part on the choice of the domain of integration, *i.e.*, inner and outer radii of the spherical domain, and limits on data resolution. The outer radius is chosen so as to maximize the ratio between the number of intramolecular and intermolecular vectors. A typical value of this radius is 50–75% of the subunit's diameter for spherical molecules. The choice of the inner radius is less crucial, provided that the origin peaks are subtracted from the Patterson functions; it is often set to zero.

The resolution range of the selected diffraction data depends on whether we are computing self- or cross-rotation functions. For self rotations, data up to the highest available resolution may be used. For cross rotations, the high-resolution limit is dictated by the degree of similarity between the probe and the actual molecules that constitute the crystal. The low-resolution limit is usually chosen so as to skip the solvent contribution.

Another parameter of interest concerns the angular resolution, which is rather specific to the fast rotation function. Although it was derived by expanding the interference function to follow the original reciprocal-space formulation as closely as possible, it may also be obtained by expanding the Patterson functions in spherical harmonics and then performing the integration (Crowther, 1972). In this way, the concept of angular resolution is more evident. In fact, the spherical harmonics play the same role in the angular domain as the imaginary exponentials do in Cartesian coordinate space. The analogue of the Miller indexes here is the label ℓ, directly related to the angular resolution. The term with $\ell = 0$ is invariant under rotations and is thus eliminated from the summation in equation (13.2.3.14). It represents the contribution of the best radial functions, in a least-squares sense, that approximate the Patterson functions within Ω. The origin peak is thus properly removed by omitting the $\ell = 0$ term, as well as a substantial component of the original function. Also, by omitting low ℓ's, the angular resolution of peaks is enhanced. These eliminations may also be done in other formulations, but never as efficiently.

The parameters discussed above are not all independent. The relationship between them stems from the behaviour of the spherical Bessel functions for small values of their argument (Watson, 1958),

$$j_\ell(2\pi hb) \simeq (2\pi hb)^\ell/(2\ell+1)!!$$

[see equation (13.2.3.8)]. So, when omitting low ℓ terms, we are also weighting down low-resolution data.

13.2.3.4. Symmetry properties of the rotation function

The overlap integral that defines $\mathcal{R}$ may be calculated by rotating P_t instead of P_s, but with the inverse rotation,

$$\begin{aligned}\mathcal{R}(\mathbf{R}) &= (1/v)\int_{\Omega} P_t(\mathbf{r})P_s(\mathbf{R}^{-1}\mathbf{r})\;\mathrm{d}^3\mathbf{r}\\ &= (1/v)\int_{\Omega} P_t(\mathbf{R}\mathbf{r})P_s(\mathbf{r})\;\mathrm{d}^3\mathbf{r}. \qquad (13.2.3.18)\end{aligned}$$

This property enables the analysis of the consequence of the symmetries of the Patterson functions upon the rotation function (Tollin *et al.*, 1966; Moss, 1985). For example, when the target and search functions are the same, a trivial symmetry of the self-rotation results: its values at $\mathbf{R}$ and $\mathbf{R}^{-1}$ are the same or, in Euler angles, at (α, β, γ) and $(180-\gamma, \beta, 180-\alpha)$. More generally, if P_t is invariant under the rotation $\mathbf{T}$, *i.e.*, $P_t(\mathbf{T}^{-1}\mathbf{r}) = P_t(\mathbf{r})$ [and similarly for the search function, $P_s(\mathbf{S}^{-1}\mathbf{r}) = P_s(\mathbf{r})$], then

$$\begin{aligned}\mathcal{R}(\mathbf{R}) &= (1/v)\int_{\Omega} P_t(\mathbf{r})P_s(\mathbf{R}^{-1}\mathbf{r})\;\mathrm{d}^3\mathbf{r}\\ &= (1/v)\int_{\Omega} P_t(\mathbf{T}^{-1}\mathbf{r})P_s(\mathbf{S}^{-1}\mathbf{R}^{-1}\mathbf{r})\;\mathrm{d}^3\mathbf{r}\\ &= (1/v)\int_{\Omega} P_t(\mathbf{r})P_s(\mathbf{S}^{-1}\mathbf{R}^{-1}\mathbf{T}\;\mathbf{r})\;\mathrm{d}^3\mathbf{r} = \mathcal{R}(\mathbf{T}^{-1}\mathbf{R}\mathbf{S}).\end{aligned} \qquad (13.2.3.19)$$

However, the actual symmetry displayed by $\mathcal{R}$ depends on the parameterization of the rotations and on the orientation of the orthonormal axes with respect to the crystal ones. Within the Euler parameterization, if the target function has an n-fold rotation axis parallel to the orthonormal z axis, then, according to equation (13.2.2.3), $\mathcal{R}$ will have a periodicity of $360/n$ along α. Similarly, a rotation axis of order n along $\mathbf{z}$ of P_s gives rise to a periodicity of $360/n$ along γ. Therefore, the amount of calculation is reduced by choosing $\mathbf{z}$ along the Patterson functions' highest rotational symmetry axes [see equation (13.2.3.11)].

13.2.4. The locked rotation function

The rotational NCS, determined with the help of the self-rotation function, may be used to enhance the signal-to-noise ratio of cross-rotation functions (Rossmann *et al.*, 1972; Tong & Rossmann, 1990). If $\{\mathbf{S}_n, n = 1, \ldots, N\}$ denotes the set of NCS rotations, including the identity, and $\mathbf{R}$ is a correct orientation of the cross rotation, then $\mathbf{S}_n\mathbf{R}$ must also correspond to a correct orientation. Here we are assuming that the rotational NCS forms a group. Otherwise, either $\mathbf{S}_n\mathbf{R}$ or $\mathbf{S}_n^{-1}\mathbf{R}$, but not both, corresponds to another correct orientation. Therefore, a function may be defined, the locked cross rotation, whose values are the average of the cross-rotation values at orientations related by the NCS:

$$\mathcal{R}_{LC}(\mathbf{R}) = \sum_{n=1}^{N}\mathcal{R}(\mathbf{S}_n\mathbf{R})/N. \qquad (13.2.4.1)$$

By redefining the target function, it can be computed as an ordinary cross rotation. Indeed, $\mathcal{R}_{LC}$ may be written in a form similar to equation (13.2.3.3),

$$\begin{aligned}\mathcal{R}_{LC}(\mathbf{R}) &= \sum_{n=1}^{N}(1/v)\int_{\Omega} P_t(\mathbf{r})P_s(\mathbf{R}^{-1}\mathbf{S}_n^{-1}\mathbf{r})\ \mathrm{d}^3\mathbf{r}/N \\ &= (1/v)\int_{\Omega}\left[\sum_{n=1}^{N}P_t(\mathbf{S}_n\mathbf{r})/N\right]P_s(\mathbf{R}^{-1}\mathbf{r})\ \mathrm{d}^3\mathbf{r}, \qquad (13.2.4.2)\end{aligned}$$

with the target Patterson function substituted by the average over the NCS of the rotated target functions. The computation of equation (13.2.4.2) is particularly simple in the case of the fast rotation function. The substitution

$$e^{(t)}_{\ell,m,n} \rightarrow \sum_{m'=-\ell}^{\ell}\left[\sum_{n=1}^{N}\mathcal{D}^{\ell}_{m,m'}(\mathbf{S}_n)/N\right]e^{(t)}_{\ell,m',n}, \qquad (13.2.4.3)$$

where we replaced the sum over $\mathbf{S}_n^{-1}$ by a sum over $\mathbf{S}_n$, because of the rearrangement theorem of group theory, gives the required target coefficients.

The same ideas may be applied to the self-rotation function. Here the NCS is assumed beforehand, with elements $\{\mathbf{I}_n, n = 1, \ldots, N\}$ in a given reference orientation. They are related to the actual NCS elements by

$$\mathbf{S}_n = \mathbf{R}_n\mathbf{I}_n\mathbf{R}_n^{-1} \qquad (13.2.4.4)$$

[see equation (13.2.2.2)]. Since each $\mathbf{S}_n$ should correspond to a local maximum of the self rotation, the function

$$\mathcal{R}_{LS}(\mathbf{R}) = \sum_{n=1}^{N}\mathcal{R}(\mathbf{R}\mathbf{I}_n\mathbf{R}^{-1})/N \qquad (13.2.4.5)$$

should also display a maximum for each $\mathbf{R}_n$, but with a noise level reduced by $(N)^{1/2}$. Equation (13.2.4.5) defines the locked self-rotation function. Its computation by fast rotation techniques is less straightforward than in the locked cross-rotation case.

13.2.5. Other rotation functions

The rotation function was hitherto described in terms of self- and cross-Patterson vectors. This is perhaps inevitable in the self-rotation case, but the problem of determining the absolute orientation of the subunits when a model structure is available may be formulated in a different way. We may try to compare directly the observed and calculated intensities or structure factors by using any criterion analogous to those employed in refinement procedures, *e.g.*, the crystallographic R factor or correlation coefficients.

When the space-group symmetry is explicitly exhibited, the structure factor corresponding to a crystal with M independent molecules in the unit cell takes the form

$$F(\mathbf{h}) = \sum_{m=1}^{M}\sum_{g=1}^{G} f_m(\mathbf{h}\mathbf{M}_g)\exp[2\pi i\mathbf{h}(\mathbf{M}_g\mathbf{r}_m + \mathbf{t}_g)], \qquad (13.2.5.1)$$

where $\mathbf{M}_g$ and $\mathbf{t}_g$ denote, respectively, the transformation matrix and the translation associated with the gth symmetry operation of the crystal space group. The corresponding intensity is

$$\begin{aligned}I(\mathbf{h}) = \sum_{m,m'=1}^{M}\ \sum_{g,g'=1}^{G}\overline{f_m(\mathbf{h}\mathbf{M}_g)}f_{m'}(\mathbf{h}\mathbf{M}_{g'})& \\ \times\exp[2\pi i\mathbf{h}(\mathbf{M}_g\mathbf{r}_m + \mathbf{t}_g - \mathbf{M}_{g'}\mathbf{r}_{m'} - \mathbf{t}_{g'})].& \qquad (13.2.5.2)\end{aligned}$$

For criteria based on amplitudes, the calculated structure factor will contain only the contribution of the rotated model,

$$F^{\text{calc}}_{\mathbf{h}}(\mathbf{R}) = f_m(\mathbf{h}\mathbf{R}), \qquad (13.2.5.3)$$

i.e., the Fourier transform of a single molecule in the crystal cell, assuming $P1$ symmetry. For criteria based on intensities, some symmetry information may be introduced,

$$I^{\text{calc}}_{\mathbf{h}}(\mathbf{R}) = \sum_{g=1}^{G}|\,f_m(\mathbf{h}\mathbf{M}_g\mathbf{R})|^2. \qquad (13.2.5.4)$$

A criterion often considered is the correlation coefficient on intensities,

$$\begin{aligned}\mathcal{R}_{\mathcal{D}}(\mathbf{R}) &= \langle(I^{\text{obs}} - \langle I^{\text{obs}}\rangle)(I^{\text{calc}} - \langle I^{\text{calc}}\rangle)\rangle \\ &\quad\times[\langle(I^{\text{obs}} - \langle I^{\text{obs}}\rangle)^2\rangle\langle(I^{\text{calc}} - \langle I^{\text{calc}}\rangle)^2\rangle]^{1/2}, \qquad (13.2.5.5)\end{aligned}$$

where $\langle\ldots\rangle$ means 'average over reflections'. It may be calculated within reasonable computing time provided that

(1) the structure factors are computed by interpolation from the Fourier transform of the isolated molecule's electron density; and

(2) an efficient sampling set of $\mathcal{R}_{\mathcal{D}}$ is defined.

$\mathcal{R}_{\mathcal{D}}$ is referred to as the direct-rotation function (DeLano & Brünger, 1995). A major advantage of this formulation is that the information stemming from already-positioned subunits may be taken into account, just by adding their contribution to the calculated intensities.

13.2.6. Concluding remarks

Each formulation of the rotation function described above has its advantages and disadvantages. The direct-space formulation [equation (13.2.3.3)] offers the possibility of modifying the Patterson function or selecting the strongest peaks to be used in the overlap integral. Also, the domain of integration may have any shape, as in the reciprocal-space formulation [equation (13.2.3.5)]. However, in both formulations, the numerical results can be somewhat imprecise because of the approximations introduced to save computing time.

When the domain of integration is spherical, as is usually the case, then the fast rotation function [equation (13.2.3.15)] is faster, more accurate and allows for angular-resolution enhancement. Moreover, since most of the computing time is spent in the calculation of the coefficients $e_{\ell,m,n}$, a library of these coefficients may be compiled to assess the models in a given molecular-replacement problem more rapidly.

The direct rotation [equation (13.2.5.5)] seems preferable to the cross-rotation function, as it includes all self-Patterson terms of the search model. However, when the order of the space group is high, the calculated intensity represents only a small fraction of the observed one, and the discriminative power of the function drops, as compared with the cross-rotation function.

Patterson searches now benefit from new supercomputers. The real problem of molecular replacement, split for convenience into rotation and translation searches, is beginning to be tackled by genuine six-dimensional searches where all orientations are tested. This may represent the end of cross-rotation and direct-rotation functions.

APPENDIX A13.2.1

Formulae for the derivation and computation of the fast rotation function

This appendix aims to present a complete set of formulae which allow the derivation and computation of the fast rotation function. They involve a particular convention for the definition of the irreducible representations of the rotation group suitable for crystallographic computations.

A13.2.1.1. Euler parameterization

By applying the group property of rotations [equation (13.2.2.2)], the Euler parameterization may be expressed as rotations around fixed axis (see Fig. 13.2.2.1*b*):

$$\begin{aligned}\mathbf{R}(\alpha,\beta,\gamma) &= \mathbf{R}(\gamma,\mathbf{p})\mathbf{R}(\beta,\mathbf{n})\mathbf{R}(\alpha,\mathbf{z})\\ &= \left[\mathbf{R}(\beta,\mathbf{n})\mathbf{R}(\gamma,\mathbf{z})\mathbf{R}(\beta,\mathbf{n})^{-1}\right]\mathbf{R}(\beta,\mathbf{n})\mathbf{R}(\alpha,\mathbf{z})\\ &= \mathbf{R}(\beta,\mathbf{n})\mathbf{R}(\gamma,\mathbf{z})\mathbf{R}(\alpha,\mathbf{z})\\ &= \left[\mathbf{R}(\alpha,\mathbf{z})\mathbf{R}(\beta,\mathbf{y})\mathbf{R}(\alpha,\mathbf{z})^{-1}\right]\mathbf{R}(\gamma,\mathbf{z})\mathbf{R}(\alpha,\mathbf{z})\\ &= \mathbf{R}(\alpha,\mathbf{z})\mathbf{R}(\beta,\mathbf{y})\mathbf{R}(\gamma,\mathbf{z}). \qquad \text{(A13.2.1.1)}\end{aligned}$$

A13.2.1.2. The $D^{\ell}_{m,m'}$ matrices

A linear representation of dimension n of the rotation group is a correspondence between rotations and matrices of order n. The matrices $D^{\ell}_{m,m'}(\mathbf{R})$, with $-\ell \le m, m' \le \ell$, are associated with the irreducible representation of dimension $2\ell+1$ $(0 \le \ell < \infty)$. They have the following properties (Brink & Satchler, 1968):

(1) Group multiplication:

$$D^{\ell}_{m,m'}(\mathbf{RR}') = \sum_{n=-\ell}^{\ell} D^{\ell}_{m,n}(\mathbf{R}) D^{\ell}_{n,m'}(\mathbf{R}'). \qquad \text{(A13.2.1.2)}$$

(2) Complex conjugation:

$$D^{\ell}_{m,m'}(\mathbf{R}^{-1}) = \overline{D^{\ell}_{m',m}(\mathbf{R})}. \qquad \text{(A13.2.1.3)}$$

(3) Euler parameterization:

$$D^{\ell}_{m,m'}(\alpha,\beta,\gamma) = d^{\ell}_{m,m'}(\beta)\exp[i(m\alpha + m'\gamma)]. \qquad \text{(A13.2.1.4)}$$

(4) Recurrence relation for the reduced matrices:

$$\begin{aligned} d^{\ell}_{m-1,m'}(\beta) &= \frac{2[m' - m\cos(\beta)]}{[(\ell-m+1)(\ell+m)]^{1/2}\sin(\beta)} d^{\ell}_{m,m'}(\beta)\\ &\quad - \left[\frac{(\ell-m)(\ell+m+1)}{(\ell-m+1)(\ell+m)}\right]^{1/2} d^{\ell}_{m+1,m'}(\beta). \qquad \text{(A13.2.1.5)}\end{aligned}$$

(5) Initial values (bottom row of d^{ℓ}):

$$d^{\ell}_{\ell,m}(\beta) = (-1)^{\ell-m}\left[\frac{(2\ell)!}{(\ell-m)!(\ell+m)!}\right]^{1/2} \sin(\beta/2)^{\ell-m}\cos(\beta/2)^{\ell+m}. \qquad \text{(A13.2.1.6)}$$

(6) Symmetry relations:

$$d^{\ell}_{-m,-m'}(\beta) = d^{\ell}_{m',m}(\beta) = (-1)^{m-m'} d^{\ell}_{m,m'}(\beta). \qquad \text{(A13.2.1.7)}$$

A13.2.1.3. Spherical harmonics

The $Y_{\ell,m}$'s, with $-\ell \le m \le \ell$ and $0 \le \ell < \infty$, constitute a complete set of functions of the unit vector $\mathbf{u}$, having the following properties (Brink & Satchler, 1968):

(1) Transformation under rotations:

$$\begin{aligned} Y_{\ell,m}(\mathbf{R}^{-1}\mathbf{u}) &= \sum_{m'=-\ell}^{\ell} D^{\ell}_{m,m'}(\mathbf{R}^{-1}) Y_{\ell,m'}(\mathbf{u})\\ &= \sum_{m'=-\ell}^{\ell} Y_{\ell,m'}(\mathbf{u})\overline{D^{\ell}_{m',m}(\mathbf{R})}. \qquad \text{(A13.2.1.8)}\end{aligned}$$

(2) Orthogonality condition:

$$\int \overline{Y_{\ell,m}(\mathbf{u})} Y_{\ell',m'}(\mathbf{u})\,\mathrm{d}^2\mathbf{u} = \delta_{\ell,\ell'}\delta_{m,m'}. \qquad \text{(A13.2.1.9)}$$

(3) Inversion:

$$Y_{\ell,m}(-\mathbf{u}) = (-1)^{\ell}\; Y_{\ell,m}(\mathbf{u}). \qquad \text{(A13.2.1.10)}$$

(4) Relation with rotation-matrix elements:

$$Y_{\ell,m}(\theta,\varphi) = i^{\ell}[(2\ell+1)/4\pi]^{1/2} D^{\ell}_{m,0}(\varphi,\theta,0), \qquad \text{(A13.2.1.11)}$$

where (θ, φ) are the polar coordinates of $\mathbf{u}$.

A13.2.1.4. Spherical Bessel functions

The j_{ℓ}'s, with $0 \le \ell < \infty$, constitute a complete set of functions having the following properties (Watson, 1958):

(1) Recurrence relation:

$$j_{\ell-1}(x) - (2\ell+1)[\,j_{\ell}(x)/x] + j_{\ell+1}(x) = 0. \qquad \text{(A13.2.1.12)}$$

(2) Initial values:

$$\begin{aligned} j_0(x) &= \sin(x)/x\\ j_1(x) &= [\sin(x) - x\ \cos(x)]/x^2. \qquad \text{(A13.2.1.13)}\end{aligned}$$

(3) Integral of a product of spherical Bessel functions:

$$\begin{aligned} U^{\ell}(p,q) &= \int_0^1 j_{\ell}(px) j_{\ell}(qx) x^2\,\mathrm{d}x\\ &= \begin{cases} [\,j_{\ell}(p) j_{\ell-1}(q) q - j_{\ell}(q) j_{\ell-1}(p) p]/(p^2 - q^2) & \text{if } p \ne q\\ \tfrac{1}{2}[\,j_{\ell}(p)^2 - j_{\ell-1}(p) j_{\ell+1}(p)] & \text{if } p = q \end{cases}\\ &= (2\ell+3)[\,j_{\ell+1}(p) j_{\ell+1}(q)]/pq + U^{\ell+2}(p,q)\\ &= \sum_{n=1}^{\infty}[2(\ell+2n) - 1][\,j_{\ell+2n-1}(p) j_{\ell+2n-1}(q)]/pq. \qquad \text{(A13.2.1.14)}\end{aligned}$$

A13.2.1.5. Expansion of $\exp(2\pi i\mathbf{sr})$

This is also called the plane-wave expansion or Laplace's expansion (Landau & Lifschitz, 1972):

$$\exp(2\pi i\mathbf{sr}) = 4\pi\sum_{\ell=0}^{\infty} i^{\ell} \sum_{m=-\ell}^{\ell} j_{\ell}(2\pi s r)\overline{Y_{\ell,m}(\hat{\mathbf{s}})} Y_{\ell,m}(\hat{\mathbf{r}}). \qquad \text{(A13.2.1.15)}$$

A13.2.1.6. Expansion of the interference function

$$\begin{aligned}
\chi_b(\mathbf{h}-\mathbf{k}\mathbf{R}^{-1}) &= (3/4\pi b^3)\int_0^b\int_0^\pi\int_0^{2\pi} \exp[2\pi i(\mathbf{h}-\mathbf{k}\mathbf{R}^{-1})\mathbf{r}]r^2\sin(\theta)\,\mathrm{d}r\,\mathrm{d}\theta\,\mathrm{d}\varphi \\
&= \sum_{\ell,\ell'=0}^{\infty}\sum_{m=-\ell}^{\ell}\sum_{m'=-\ell'}^{\ell'} i^{\ell-\ell'}\overline{Y_{\ell,m}(\hat{\mathbf{h}})}Y_{\ell',m'}(\hat{\mathbf{k}}) \\
&\quad\times(12\pi/b^3)\int_0^b j_\ell(2\pi hr)\,j_{\ell'}(2\pi kr)r^2\,\mathrm{d}r \\
&\quad\times\int_0^\pi\int_0^{2\pi} Y_{\ell,m}(\hat{\mathbf{r}})\overline{Y_{\ell',m'}(\mathbf{R}^{-1}\hat{\mathbf{r}})}\sin(\theta)\,\mathrm{d}\theta\,\mathrm{d}\varphi \\
&= \sum_{\ell=0}^{\infty}\sum_{m=-\ell}^{\ell}\sum_{\ell'=0}^{\infty}\sum_{m'=-\ell'}^{\ell'} i^{\ell-\ell'}\overline{Y_{\ell,m}(\hat{\mathbf{h}})}Y_{\ell',m'}(\hat{\mathbf{k}}) \\
&\quad\times(12\pi/b^3)\int_0^b j_\ell(2\pi hr)\,j_{\ell'}(2\pi kr)r^2\,\mathrm{d}r \\
&\quad\times\sum_{m''=-\ell'}^{\ell'}\int_0^\pi\int_0^{2\pi} Y_{\ell,m}(\hat{\mathbf{r}})\overline{Y_{\ell',m''}(\hat{\mathbf{r}})}\sin(\theta)\,\mathrm{d}\theta\,\mathrm{d}\varphi\; D^{\ell'}_{m'',m'}(\mathbf{R}) \\
&= \sum_{\ell=0}^{\infty}\sum_{m'=-\ell}^{\ell}\overline{Y_{\ell,m}(\hat{\mathbf{h}})}Y_{\ell,m'}(\hat{\mathbf{k}})12\pi U^\ell(2\pi hb,2\pi kb)D^\ell_{m,m'}(\mathbf{R}).
\end{aligned}\tag{A13.2.1.16}$$

Chapter 13.3. Translation functions

L. Tong

13.3.1. Introduction

A structure determination by the molecular-replacement method traditionally proceeds in two steps (Rossmann, 1972, 1990, 2001). The first step involves the determination of the orientation of the search model in the crystal unit cell by the rotation functions (see Chapter 13.2). Once the orientation of the search model is known, translation functions are employed in the second step to determine the location of the model in the crystal unit cell. This essentially reduces a six-dimensional problem (three rotational and three translational degrees of freedom) to two three-dimensional problems, which are computationally more manageable. With the speed of modern computers, a strict division between the rotational and the translational components of a molecular-replacement structure solution may no longer be necessary (see Section 13.3.7).

Translation functions are normally formulated to achieve minimum or maximum values when the search model is at its correct position in the crystal unit cell. As with the rotation problem, the translation problem is frequently solved as a search. The positional parameters of the model are varied in the unit cell, generally on a grid. Translation functions are evaluated at these search grid points in order to identify those that minimize or maximize the functions.

Most translation functions involve a comparison between the observed structure-factor amplitudes (or squared amplitudes) and those calculated based on the search model. The *R* factor and the correlation coefficient can be used as indicators for translation searches (Section 13.3.2). The correlation between the observed Patterson map and that based on the search model is the foundation of another translation function (Section 13.3.3). If phase information is available from other sources, the correlation between the electron-density maps is the basis for phased translation functions (Section 13.3.4). Proper packing of the search model in the crystal unit cell is an essential component of a solution to the translation problem (Section 13.3.5). The power of the translation functions can be enhanced in the presence of noncrystallographic symmetry (Section 13.3.8).

Besides *R*-factor, correlation-coefficient and Patterson-correlation functions, target functions based on the principle of maximum likelihood have been found to be powerful indicators for molecular-replacement calculations (Read, 2001; McCoy *et al.*, 2005, 2007), and have been successful in helping determine structures where traditional molecular-replacement target functions have failed.

13.3.2. *R*-factor and correlation-coefficient translation functions

The crystallographic *R* factor is often used as an indicator in translation searches. It is a measure of the percentage difference between the observed (F_h^o) and the calculated (F_h^c) structure-factor amplitudes,

$$R_F = 100 \times \sum_h \left|F_h^o - k_F F_h^c\right| \Big/ \sum_h F_h^o. \qquad (13.3.2.1)$$

A similar *R* factor can be defined based on the square of the structure-factor amplitudes, *i.e.* an *R* factor based on intensity,

$$R_I = 100 \times \sum_h \left|I_h^o - k_I I_h^c\right| \Big/ 2\sum_h I_h^o. \qquad (13.3.2.2)$$

A factor of 2 is introduced in equation (13.3.2.2) to make R_I values fall in the same range as R_F. In equations (13.3.2.1) and (13.3.2.2) k_F and k_I are scale factors that bring the observed and the calculated structure factors to the same level. If these scale factors are calculated in shells of equal reciprocal volume, they can compensate for differences in the displacement factors between the observed and the calculated structure-factor amplitudes.

In addition to the *R* factor, the correlation coefficient between the observed and the calculated structure factors is also used in translation searches. Like the *R* factors, correlation coefficients can be defined based on the amplitude or the intensity of the reflections, and that based on the amplitude is shown below.

$$\begin{aligned} cc_F &= \frac{\sum_h \left(F_h^o - \langle F_h^o\rangle\right)\left(F_h^c - \langle F_h^c\rangle\right)}{\left[\sum_h \left(F_h^o - \langle F_h^o\rangle\right)^2 \left(F_h^c - \langle F_h^c\rangle\right)^2\right]^{1/2}} \\ &= \frac{\sum_h F_h^o F_h^c - \sum_h F_h^o \sum_h F_h^c / N}{\left\{\left[\sum_h \left(F_h^o\right)^2 - \left(\sum_h F_h^o\right)^2/N\right]\left[\sum_h \left(F_h^c\right)^2 - \left(\sum_h F_h^c\right)^2/N\right]\right\}^{1/2}}. \end{aligned} \qquad (13.3.2.3)$$

In (13.3.2.3), N is the number of reflections that are used in the calculation and $\langle F_h\rangle$ denotes the average structure-factor amplitude over the reflections. Unlike the *R* factors, the correlation coefficients do not depend on the overall scale factor between the observed and the calculated structure factors. However, they can be affected by large differences in the overall displacement factors between the observed and the calculated structure factors. The correlation coefficient based on intensity can be calculated by the fast Fourier transform (FFT) technique for translation-function calculations (Navaza & Vernoslova, 1995).

In order to evaluate *R* factors and correlation coefficients for a translation search, structure factors need to be calculated for the search model, with a given orientation, at different positions in the unit cell. For this special case, where only the positional parameters of the search model are varied, the calculation of the structure factors can be simplified (Nixon & North, 1976; Rae, 1977). The structure-factor equation can be written as a double summation – first over the atoms in one asymmetric unit of the unit cell and then over all the asymmetric units,

$$\bar{F}_h^c = \sum_n \sum_j f_j \exp\left\{2\pi i h\left(\left[T_n\right]x_j + t_n\right)\right\}, \qquad (13.3.2.4)$$

where j goes over all the atoms in the asymmetric unit and n goes over all the crystallographic asymmetric units. The nth crystallographic symmetry operator is given by

$$x_n = \left[T_n\right]x + t_n, \qquad (13.3.2.5)$$

where $\left[T_n\right]$ is the rotational component and t_n is the translational component of the symmetry operator.

For simplicity, first consider the case where there is only one molecule in the asymmetric unit. In the translation search, the model will be placed at different positions in the unit cell,

Copyright © 2012 International Union of Crystallography

$$x_j = x_j^0 + v_0, \tag{13.3.2.6}$$

where v_0 is a translation vector which is applied to move the model from its starting position (x_j^0). Substituting x_j in (13.3.2.6) into (13.3.2.4) gives

$$\bar{F}_h^c = \sum_n \bar{f}_{h,n} \exp\big(2\pi i h\big[T_n\big]v_0\big), \tag{13.3.2.7}$$

where $\bar{f}_{h,n}$ is the structure factor calculated based only on the nth symmetry-related molecule,

$$\bar{f}_{h,n} = \sum_j f_j \exp\big\{2\pi i h\big(\big[T_n\big]x_j^0 + t_n\big)\big\}. \tag{13.3.2.8}$$

It can be calculated by placing the search model at the starting position in a $P1$ unit cell having the same cell dimensions as the crystal unit cell. The structure factors calculated for this $P1$ cell are related to $\bar{f}_{h,n}$ by

$$\bar{f}_{h,n} = \exp(2\pi i h t_n)\bar{f}_{h[T_n],\,1}. \tag{13.3.2.9}$$

Therefore, the summation over the atoms in the structure-factor calculation, a rather time-consuming process, needs to be performed only once, for the search model at the starting position. Subsequent structure-factor calculations after translation of the model are no longer dependent on the number of atoms present in the unit cell [equation (13.3.2.7)]. The starting position is usually chosen such that the centre of the search model is at (0, 0, 0). Then the vector that is determined from the translation searches will define the centre of the model in the unit cell.

Equation (13.3.2.7) can be generalized to allow for the presence of other molecules that are to remain stationary during the translation search:

$$\bar{F}_h^c = \bar{A}_h + \sum_n \bar{f}_{h,n} \exp(2\pi i h[T_n]v_0), \tag{13.3.2.10}$$

where $\bar{A}_h$ is the contribution from the stationary molecules. This formulation is useful if there is more than one molecule in the asymmetric unit. The position of one of the molecules can be determined first, and the model is then included as a stationary molecule for the position search of the next molecule. Incorporation of the contribution from stationary molecules can also improve the quality of the translation function (Zhang & Matthews, 1994).

Equation (13.3.2.7) can also be generalized to allow for the presence of two (or more) search models that are to move independently of each other during the translation search. However, this will generally lead to a six- (or more) dimensional problem and is expensive in computation time. With improvements in computer technology (especially parallel processing), it may be feasible to carry out such searches in special cases. However, this aspect of translation functions will not be discussed further here.

13.3.3. Patterson-correlation translation function

Besides the R factor and the correlation coefficient, another commonly used translation search indicator is based on the correlation between the observed and the calculated Patterson maps (Crowther & Blow, 1967; Tong, 1993; Navaza & Vernoslova, 1995). Rotation functions are based on the overlap of only a subset of the interatomic vectors in the Patterson map, *i.e.* only those near the origin of the unit cell, which generally contain the self vectors within each molecule. The correct orientation and position of a search model in the crystal unit cell should lead to the maximal overlap of both the self and the cross vectors, *i.e.* maximal overlap between the observed (P^o) and the calculated (P^c) Patterson maps throughout the entire unit cell (Tong, 1993),

$$\begin{aligned} PC &= \int_\Omega P^o(u)P^c(u)\,\mathrm{d}u \\ &= \sum_h (F_h^o)^2 |\bar{F}_h^c|^2. \end{aligned} \tag{13.3.3.1}$$

The calculated structure factor is a function of the translation vector v_0 [equation (13.3.2.10)]. Combining equations (13.3.2.10) and (13.3.3.1) gives

$$\begin{aligned} PCTF(v_0) = {} & \sum_h (F_h^o)^2 \big|A_h\big|^2 + \sum_h \sum_n (F_h^o)^2 \big|\bar{f}_{h,n}\big|^2 \\ & + 2\sum_h \sum_n (F_h^o)^2 \bar{A}_h \bar{f}_{h,n}^* \exp(-2\pi i h[T_n]v_0) \\ & + \sum_h \sum_n \sum_{m\neq n} (F_h^o)^2 \bar{f}_{h,n} \bar{f}_{h,m}^* \exp\big\{-2\pi i h\big(\big[T_m\big] - \big[T_n\big]\big)v_0\big\}. \end{aligned} \tag{13.3.3.2}$$

The first two terms in equation (13.3.3.2) contribute a constant to the correlation and are generally ignored in this calculation (but see Section 13.3.8). The Patterson-correlation translation function is therefore a Fourier transform, with $h[T_n]$ (from the third term) and $h([T_m] - [T_n])$ (from the fourth term) as the indices. This function can be evaluated quickly by the FFT technique. The term $h([T_m] - [T_n])$ often leads to the doubling of the original reflection indices. For example, $h([T_1] - [T_2])$ will give rise to ($2h$, 0, $2l$) for monoclinic space groups (b-unique setting). Therefore, the Patterson-correlation Fourier transform should normally be sampled with a grid size about 1/6 of the maximum resolution of the reflection data used in the calculation.

A disadvantage of the Patterson-correlation translation function as formulated in equation (13.3.3.2) is that the results from the calculation are on an arbitrary scale. This makes it difficult to compare results from different calculations. The R factor or the correlation coefficient can be calculated for the top peaks in the Patterson-correlation translation function [equation (13.3.3.2)] to place the results on an 'absolute' scale. Alternatively, the correlation, as defined by equation (13.3.3.1), can be normalized to become a Patterson-correlation coefficient (Harada *et al.*, 1981),

$$PC = \frac{\sum_h \big(F_h^o\big)^2 \big|\bar{F}_h^c\big|^2}{\Big[\sum_h \big(F_h^o\big)^4 \sum_h \big|\bar{F}_h^c\big|^4\Big]^{1/2}}. \tag{13.3.3.3}$$

This correlation coefficient is equivalent to that defined by equation (13.3.2.3) for reflection intensities (Fujinaga & Read, 1987). The evaluation of the $(\sum_h |\bar{F}_h^c|^4)^{1/2}$ term in the denominator of equation (13.3.3.3) is, however, time consuming, since the FFT technique cannot be applied directly. This term can be approximated by an expression which also measures the packing of the search molecules in the crystal (see Section 13.3.5).

The intramolecular vectors can be removed (Crowther & Blow, 1967) from the Patterson maps by subtracting, after appropriate scaling, the structure factors calculated from individual molecules [equation (13.3.2.8)].

The translation functions, as defined above, are based on the structure-factor amplitudes. Normalized structure factors (E's) may provide better results under certain circumstances, since they increase the weight of the high-resolution reflections in the translation function (Tollin, 1966; Harada *et al.*, 1981; Tickle, 1985). Since the Patterson-correlation translation function is also based on reflection intensities, the 'large term' approach can be used to accelerate the calculation (Tollin & Rossmann, 1966).

13.3.4. Phased translation function

If an atomic model needs to be placed in an electron-density map that has been obtained through other methods (*e.g.* the multiple-isomorphous-replacement method or partial model phases), the phased translation function can be used (Colman *et al.*, 1976; Read & Schierbeek, 1988; Bentley & Houdusse, 1992; Tong, 1993; Zhang & Matthews, 1994). It is essentially based on the correlation between observed and calculated electron-density values throughout the unit cell:

$$PTF(v_0) = \sum_h \sum_n \bar{F}^o_h \bar{f}^*_{h,n} \exp\big(-2\pi i h\big[T_n\big]v_0\big). \qquad (13.3.4.1)$$

Therefore, the phased translation function can also be evaluated by the FFT technique. As with the Patterson-correlation translation function, the phased translation function can be placed on an 'absolute' scale by introducing appropriate normalizing factors or by converting the results to R factors or correlation coefficients. It should be noted that the prior phase could be in the wrong hand, so both $\bar{F}^o_h$ and $(\bar{F}^o_h)^*$ may need to be tried in the phased translation function, especially if the phase information is derived from isomorphous replacement.

The stationary molecules contribute a constant to the phased translation function and are not shown in equation (13.3.4.1). However, the phase information from the stationary molecules can be applied to the observed structure-factor amplitudes, and the phased translation function, rather than the Patterson-correlation translation function, can be used in the search for additional molecules (Read & Schierbeek, 1988; Driessen *et al.*, 1991; Bentley & Houdusse, 1992). This could prove especially useful in locating the last few molecules in cases where there are several molecules in the asymmetric unit. Modified phased translation functions have been designed to locate fragments in the electron-density map (Cowtan, 1998).

13.3.5. Packing check in translation functions

A correct molecular-replacement solution should lead to the placement of the search model at the correct orientation and position in the crystal unit cell. For this solution, there should be no or minimal steric clashes among the crystallographically related and noncrystallographically related molecules in the unit cell (unless there are large conformational changes for the model in the crystal unit cell). Therefore, proper packing of the search model in the crystal unit cell is an important component of the molecular-replacement structure solution.

The packing of the search model in the unit cell can be estimated by determining the electron-density overlap among the molecules. This overlap can be calculated numerically, given the molecular envelope (Hendrickson & Ward, 1976). It can also be estimated by an analytical function (Harada *et al.*, 1981),

$$O(v_0) = \sum_h \big|\bar{F}^c_h(v_0)\big|^2 \Big/ N \sum_h \big|\bar{f}_{h,1}\big|^2, \qquad (13.3.5.1)$$

where N is the number of crystallographic symmetry operators. This overlap function assumes a value of 1 when there is no overlap among the molecules, and higher values when there is overlap. This function has been used to replace the $(\sum_h |\bar{F}^c_h|^4)^{1/2}$ term in the denominator of equation (13.3.3.3) (Harada *et al.*, 1981). Consequently, those positions that lead to steric clashes among the molecules will be down-weighted, thereby increasing the signal for the correct solution.

The overlap functions provide an overall estimate for the packing of the search model in the unit cell. A more detailed packing analysis can be based on the checking of atomic contacts (Tong, 1993). For example, the number of $C_\alpha \cdots C_\alpha$ contacts below a pre-specified distance cutoff (normally between 2 to 3 Å) in a protein crystal can be determined. Too many such contacts would indicate significant overlap of the molecules. For nucleic acid structures, a set of representative atoms (for example, P, C_1') can be selected from each nucleotide for this packing analysis.

13.3.6. The unique region of a translation function (the Cheshire group)

The region of the unit cell that should be covered during a translation search does not generally correspond to the asymmetric unit of the space group. Since the search model has a defined orientation, it can only reside in one of the asymmetric units in the unit cell. Lacking knowledge as to which asymmetric unit the model occupies, the entire unit cell would need to be searched. However, most space groups possess alternative origins, which means the position of a molecule in the unit cell can only be determined to within certain sets of translations. For example, in space group $P2_12_12_1$, there are eight alternative origins at $(0,0,0)$, $(\frac{1}{2},0,0)$, $(0,\frac{1}{2},0)$, $(0,0,\frac{1}{2})$, $(\frac{1}{2},\frac{1}{2},0)$, $(\frac{1}{2},0,\frac{1}{2})$, $(0,\frac{1}{2},\frac{1}{2})$ and $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. This implies that the region that should be searched to locate a molecule need only be $\frac{1}{8}$ of the volume of the unit cell [for example, $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$]. In addition, for polar space groups, the position of the molecule along the polar axis is arbitrary. The symmetry, as defined by these unique regions, is also known as the Cheshire group (Hirshfeld, 1968), and has been defined for all the 230 space groups.

Once the first molecule is positioned, the origin of the unit cell is fixed as well. The search for subsequent molecules will need to cover the entire unit cell, unless the crystal lattice is centred.

13.3.7. Combined molecular replacement

The traditional division of the molecular-replacement problem into two steps is partly due to limited computer power. Such a division has placed more pressure on the rotation function, since generally only a few rotation angles are examined by translation functions. The correct orientation, therefore, needs to be among the top few peaks either directly in the rotation functions or after Patterson-correlation refinement (Brünger, 1990).

With modern computers, it is no longer necessary to maintain the strict division between the rotational and the translational components. Even though a full six-dimensional search is still generally impractical, a limited six-dimensional search can certainly be performed (Navaza, 1994; Tong, 1996*a*; Sheriff *et al.*, 1999; Jogl *et al.*, 2001). Target functions that can be evaluated quickly with the FFT technique are preferred for this purpose. Otherwise, the exploration of rotational degrees of freedom (Fujinaga & Read, 1987) or the reflection data that are used in the calculation (Rabinovich & Shakked, 1984) will be limited.

An automated molecular-replacement protocol has been implemented which automatically examines the top peaks in the rotation function by translation functions (Navaza, 1994). This protocol has proven to be remarkably powerful. It assumes that the correct rotation solution is near the top peaks in the rotation function. A more general assumption is that the correct rotation for the search model should produce high values in the rotation function, even though they may not be near peaks in the rotation function. An error of 6° between the correct rotation angles and the peak in the rotation function, which often occurs, can make it impossible to obtain the correct translation-function solution (Fujinaga & Read, 1987).

The combined-molecular-replacement protocol (Tong, 1996*a*; Jogl *et al.*, 2001) therefore consists of examining all the grid points in the rotation function with heights greater than a defined cutoff value using the Patterson-correlation translation function. The top peaks (usually 20 to 50) in each translation function are all examined as possible solutions. The results from these translation functions are converted to the R factor or the correlation coefficient, enabling comparisons among the various orientations. This protocol allows the automatic examination of not only the top peaks in the rotation functions, but also those angles that produce high rotation-function values. In addition, packing of the model in the crystal is examined automatically to eliminate those solutions that have severe clashes among the molecules (see Section 13.3.5). This generalized protocol has proven more powerful than conventional methods in structure determinations (Tong, 1996*a*; Wu *et al.*, 1997). An alternative approach, examining the neighbourhood surrounding the rotation-function peaks, is also possible (Urzhumtsev & Podjarny, 1995).

Stochastic or genetic algorithms have also been used successfully to simultaneously sample the six degrees of freedom (Chang & Lewis, 1997; Kissinger *et al.*, 1999; Glykos & Kokkinidis, 2000).

13.3.8. The locked translation function

In the presence of noncrystallographic symmetry (NCS), locked self-rotation functions can be used to determine the orientation of the NCS elements in the crystal unit cell (Tong & Rossmann, 1990). Often, an atomic model for the monomer of the NCS assembly is available, but not a model of the entire assembly. This atomic model can be used in ordinary cross-rotation-function calculations. A more powerful technique is to use the locked cross-rotation function, which can define the orientations of all the molecules within the assembly at the same time (Tong & Rossmann, 1997). With the knowledge of the orientations, several translation searches are needed to locate the individual monomers of the assembly. For cases where the assembly has high NCS, the translation searches to locate the first few molecules may not be very successful, since the search model only represents a small portion of the diffracting power of the crystal.

A locked translation function takes into account contributions from all the monomers of the assembly at the same time (Tong, 1996*b*). It can determine the position of the monomer search model relative to the centre of the NCS assembly. With this knowledge, the entire assembly can be generated and can then be used in an ordinary translation search to locate the centre of this NCS assembly in the crystal unit cell.

Given the atomic model, X_j^0 (in Cartesian coordinates), for the monomer at a starting position and the rotation, $[F]$, that brings it into the same orientation as that of a monomer in the standard orientation, the model of the entire assembly in the standard orientation is given by

$$X_{j,m} = [I_m]([F]X_j^0 + V_0), \tag{13.3.8.1}$$

where V_0 is a translation vector and the centre of the assembly is placed at (0, 0, 0). $[I_m]$ $(m = 1, \ldots, M)$ is the set of rotation matrices for the NCS point group in the standard orientation. The correct translation vector should give rise to the maximal overlap between the self vectors within the NCS assembly and the observed Patterson map. This overlap is given by the second term of equation (13.3.3.2). The locked translation function is therefore defined as [a comparison with equation (13.3.2.9) showing that the summation over the crystallographic symmetry operators can be omitted]

$$\begin{aligned} LTF(V_0) = {} & \sum_h \sum_m (F_h^o)^2 \mid \overline{f}_{h,m}|^2 \\ & + \sum_h \sum_m \sum_{n \neq m} (F_h^o)^2 \overline{f}_{h,m}\, \overline{f}^*_{h,n} \exp\{-2\pi i h([\theta_n] - [\theta_m])V_0\}, \end{aligned} \tag{13.3.8.2}$$

where

$$\overline{f}_{h,m} = \sum_j f_j \exp(2\pi i h[\theta_m][F]X_j^0) \tag{13.3.8.3}$$

and

$$[\theta_m] = [\alpha][E][I_m]. \tag{13.3.8.4}$$

$[E]$ is the rotation matrix that brings the standard orientation to that of the assembly in the crystal and $[\alpha]$ is the de-orthogonalization matrix (Rossmann & Blow, 1962). Equation (13.3.8.2) can be evaluated indirectly by the FFT technique (Tong, 1996*b*). As with the Patterson-correlation translation function, equation (13.3.8.2) can be converted to a correlation coefficient, although the evaluation will become more time-consuming. It should be noted that equation (13.3.8.2) bears much resemblance to equation (13.3.3.2), with the interchange of the crystallographic quantities $([T_n], \overline{f}_{h,n})$ and the noncrystallographic quantities $([\theta_m], \overline{f}_{h,m})$.

13.3.9. Miscellaneous translation functions

A variety of translation functions have been developed for special purposes. For example, a function has been proposed that can determine the translational component along an (NCS) twofold axis (Rossmann & Blow, 1962).

If initial phase information is available for a crystal that possesses NCS, averaging among the NCS monomers is a powerful technique for improving the phase information (Rossmann, 1990). Accurate parameters for the NCS elements (orientation and position) are essential for this averaging process. The orientations of the NCS elements can often be determined by self-rotation functions. The positions of the NCS elements can be determined by a special translation function based on the electron-density overlap (in a spherical volume) of NCS-related monomers (Tong, 1993):

$$T([C], s_1, s_2) = \sum_h \sum_p \overline{F}_h \overline{F}_p G_{hp} \exp(-2\pi i h s_1) \exp(-2\pi i p s_2), \tag{13.3.9.1}$$

where s_1 and s_2 are the centres of two molecules related by NCS, and $[C]$ is the rotation matrix for the NCS. This equation can be used to obtain an initial estimate for the position of the NCS axis (given its orientation) (Tong, 1993), to identify positions related by the NCS (Blow *et al.*, 1964) and to refine the NCS parameters iteratively (Tong *et al.*, 1992, 1997; Tong & Rossmann, 1997).

Chapter 13.4. Noncrystallographic symmetry averaging of electron density for molecular-replacement phase refinement and extension

M. G. Rossmann and E. Arnold

13.4.1. Introduction

Electron-density averaging for phasing crystal structures has become a widespread and nearly routine technique. High noncrystallographic symmetry (NCS) permits the solution of structures using relatively poor and even *ab initio* phasing starts, while lower NCS electron-density averaging can significantly improve initial phases obtained by techniques such as isomorphous replacement, anomalous scattering, or molecular replacement. Implicit in any averaging is solvent flattening in the regions not available for NCS averaging. Indeed, if all parts of the unit cell were consistent with the NCS, the symmetry would be crystallographic and valid throughout the crystal lattice.

A number of generalized averaging programs and software packages have been developed for macromolecular crystal structure analyses. Ease of use, coupled with relatively convenient definition of molecular envelopes, as well as enormous advances in computer technology, have facilitated the application of symmetry averaging to a diverse set of crystallographic problems. Averaging of separate domains in multidomain protein structures that can be divided into segments and averaging among multiple crystal forms is becoming increasingly common.

Extension of phases to higher resolution by symmetry averaging of electron density, coupled with solvent flattening, has been applied to numerous problems. The power of phase extension has been especially impressive in many cases involving high NCS, such as icosahedral virus structures. The overall power for phase improvement of averaging, combined with other density-modification techniques, such as solvent levelling, has been found to depend upon the degree of NCS, the solvent content of the crystals, and the quality and completeness of experimental data. Similar averaging methodology can be used for structure analysis by other imaging techniques, such as electron microscopy.

This chapter discusses the underlying principles of electron-density averaging for macromolecular crystallographic phase improvement and describes procedures for computer implementation of these techniques.

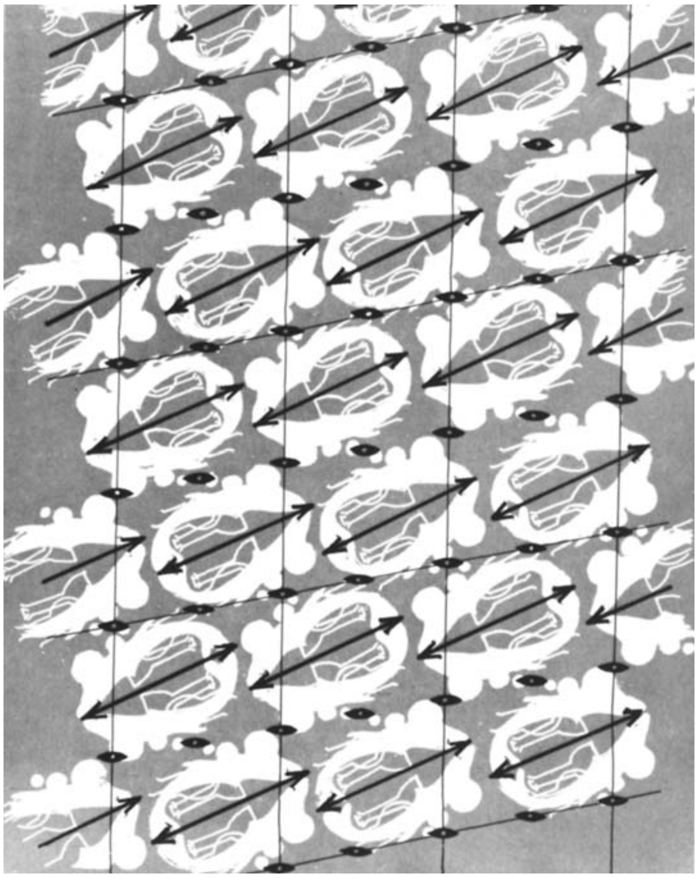

Figure 13.4.2.1
The two-dimensional periodic design shows crystallographic twofold axes perpendicular to the page and local noncrystallographic rotation axes in the plane of the paper (design by Audrey Rossmann). [Reprinted with permission from Rossmann (1972). Copyright (1972) Gordon & Breach.]

13.4.2. Noncrystallographic symmetry (NCS)

Crystallographic symmetry is valid for the infinite crystal lattice. Any crystallographic symmetry element relates all points within the crystal to equivalent points elsewhere. In contrast, an NCS operator is valid only locally within a finite volume (Fig. 13.4.2.1); if a periodic structure is superimposed on itself after operation with an NCS operator, it will superimpose only within the envelope[1] defining the limits of the local symmetry.

A product of superimposed periodic structures will be nonperiodic, containing only the point symmetry of the noncrystallographic operators (Fig. 13.4.2.2). This fact can frequently be used to select a molecular envelope that was not obvious prior to noncrystallographic averaging [see *e.g.* Buehner *et al.* (1974) or Lin *et al.* (1986)]. Although no knowledge of the crystallographic envelope is needed for this first averaging, it is necessary to determine it for the averaged molecular structure within the crystallographic cell to permit Fourier back-transformation.

There must be space between the confining envelopes governed by the local symmetry. Only the crystallographic symmetry is valid within this space. In the limit, when this space has diminished to zero, the local symmetry will have become a true crystallographic operator.

The definition of NCS can be extended to symmetry that relates similar objects in different crystal lattices. An operation that relates an object in one lattice to an equivalent object in another lattice will apply only to the chosen objects in each lattice. Beyond the confines of the chosen objects, there will be no coincidence of pattern.

Two kinds of NCS elements may be defined: proper and improper. The former satisfies a closed point group [*e.g.* a 17-fold rotation as occurs in tobacco mosaic virus disk protein

---

[1] In this chapter, 'envelope' will be used to describe the external surface or boundary of a molecule, while 'mask' will be used to denote the three-dimensional distribution of grid points that have been assigned within the molecular surface.

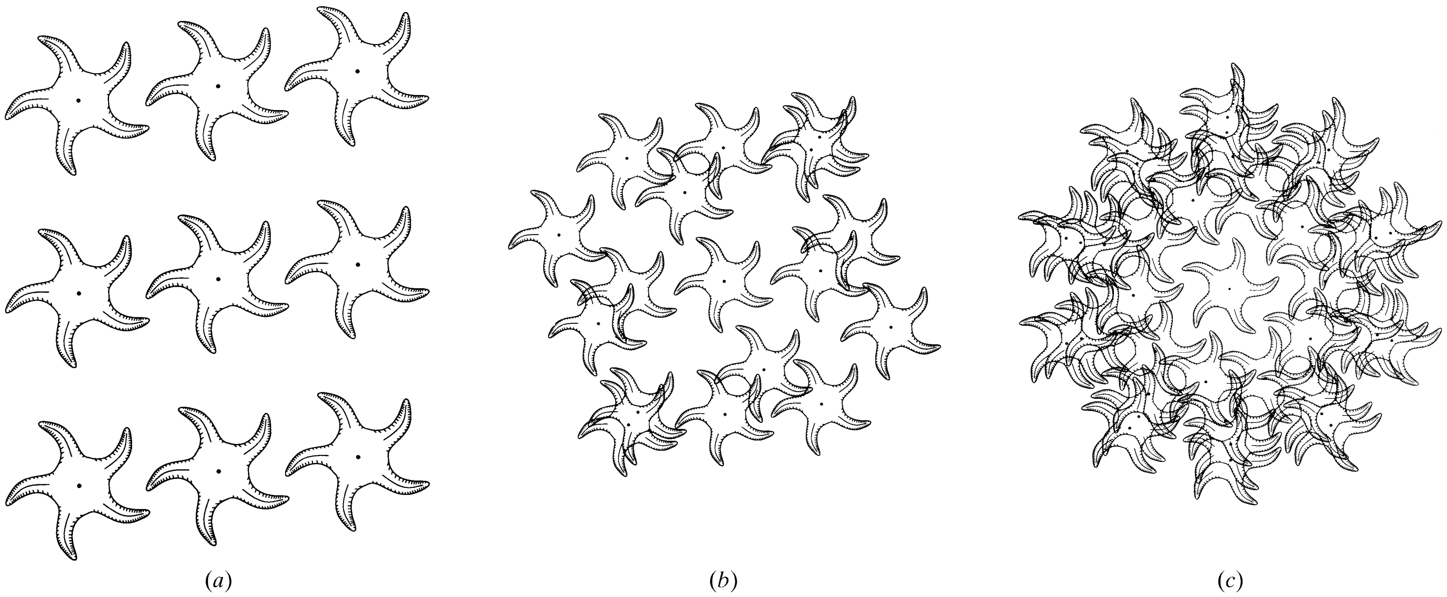

Figure 13.4.2.2
(*a*) NCS in a triclinic cell. (*b*) Superposition of the pattern in (*a*) on itself after operation with the noncrystallographic fivefold axis. (*c*) Superposition of the pattern in (*a*) on itself after a rotation of one-fifth, two-fifths, three-fifths and four-fifths. Note that the sum or product of periodic patterns is aperiodic and in (*c*) has the point symmetry of the noncrystallographic operation. [Reprinted with permission from Rossmann (1990).]

(Champness *et al.*, 1976)]. Here, it does not matter whether a rotation axis is applied right- or left-handedly; the result is indistinguishable. On the other hand, the relationship between different molecules in a crystallographic asymmetric unit is unlikely to be a closed point group. Thus, a rotation in one direction (followed by a translation) might achieve superposition of the two molecules, while a rotation in the opposite direction would not. This is called an improper NCS operator. An operation which takes a molecule in one unit cell to that in another unit cell (initially, the cells are lined up with, say, their orthogonalized *a*, *b* and *c* axes parallel) must equally be an improper rotation.

The position in space of a noncrystallographic rotation symmetry operator can be arbitrarily assigned. The rotation operation will orient the two molecules similarly. A subsequent translation, whose magnitude depends upon the location of the NCS operator, will always be able to superimpose the molecules (Fig. 13.4.2.3). Nevertheless, it is possible to select the position of the NCS axis such that the translation is a minimum, and that will occur when the translation is entirely parallel to the noncrystallographic rotation axis.

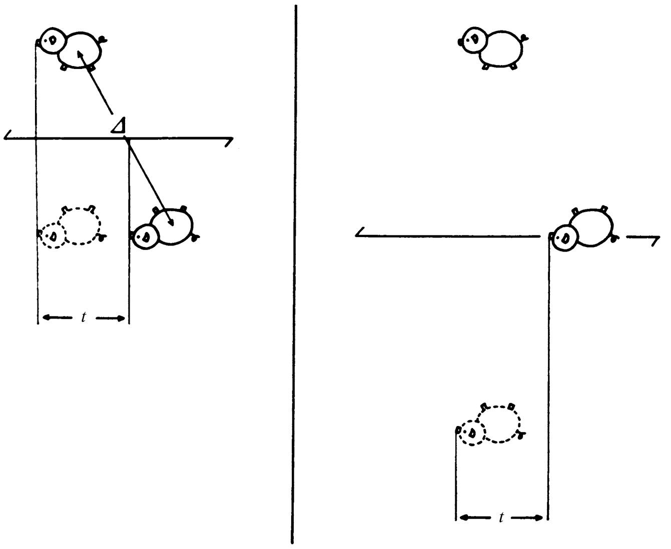

Figure 13.4.2.3
The position of the twofold rotation axis which relates the two piglets is completely arbitrary. The diagram on the left shows the situation when the translation is parallel to the rotation axis. The diagram on the right has an additional component of translation perpendicular to the rotation axis, but the component parallel to the axis remains unchanged. [Reprinted with permission from Rossmann *et al.* (1964).]

The position of an NCS axis, like everything else in the unit cell, must be defined with respect to a selected origin. Consider the noncrystallographic rotation defined by the 3×3 matrix [C]. Then, if the point $\mathbf{x}$ is rotated to $\mathbf{x}'$ (both defined with respect to the selected origin and axial system),

$$\mathbf{x}' = [\mathrm{C}]\mathbf{x} + \mathbf{d},$$

where $\mathbf{d}$ is a three-dimensional vector which expresses the translational component of the NCS operation. The magnitude of the components of $\mathbf{d}$ is quite arbitrary unless the position of the rotation axis is defined. If the rotation axis represents a proper NCS element, there will exist a point $\mathbf{x}$ on the rotation axis, when positioned to eliminate translation, such that it is rotated onto $\mathbf{x}'$. It follows that for such a point

$$\mathbf{x} = [\mathrm{C}]\mathbf{x} + \mathbf{d},$$

from which $\mathbf{d}$ can be determined if the position of the molecular centre is known. Note that $\mathbf{d} = 0$ if, and only if, the noncrystallographic rotation axis passes through the crystallographic origin.

The presence of proper NCS in a crystal can help phase determination considerably. Consider, for example, a tetramer with 222 symmetry. It is not necessary to define the chemical limits of any one polypeptide chain as the NCS is true everywhere within the molecular envelope and the boundaries of the polypeptide chain are irrelevant to the geometrical considerations. The electron density at every point within the molecular envelope (which itself must have 222 symmetry) can be averaged among all four 222-related points without any chemical knowledge of the configuration of the monomer polypeptide. On the other hand, if there is only improper NCS, then the envelope must define the limits of one noncrystallographic asymmetric unit, although the crystallographic asymmetric unit contains two or more such units.

13.4.3. Phase determination using NCS

The molecular replacement method [*cf.* Rossmann & Blow (1962); Rossmann (1972, 1990); Argos & Rossmann (1980); Rossmann & Arnold (2001)] is dependent upon the presence of NCS, whether it relates objects within one crystal lattice or between crystal lattices. The NCS rotational relationship in real space is exactly mimicked in reciprocal space. Local symmetry in real space has the equivalent effect of rotating a reciprocal lattice onto itself or another (with origins coincident), such that the integral reciprocal-lattice points of one reciprocal space coincide with non-integral reciprocal-lattice positions in the other. As the reciprocal lattice samples the Fourier transform of a molecule only at finite and integral reciprocal-lattice points, the effect of an NCS operation is to permit sampling of the molecular transform at intermediate non-integral reciprocal-lattice positions. If such sampling occurs frequently enough, it will constitute a plot of the continuous transform of the molecule and, hence, amount to a structure determination.

Whenever a molecule exists more than once either in the same unit cell or in different unit cells, then error in the molecular electron-density distribution due to error in phasing can be reduced by averaging the various molecular copies. The number of such copies, N, is referred to as the noncrystallographic redundancy. As the NCS is, by definition, only local (often pertaining to a particular molecular centre), there are holes and gaps between the averaged density, which presumably are solvent space between molecules. Thus, the electron density can be improved both by averaging electron density and by setting the density between molecules to a low, constant value ('solvent flattening'). Phases calculated by Fourier back-transforming the improved density should be more accurate than the original phases. Hence, the observed structure amplitudes (suitably weighted) can be associated with the improved phases, and a new and improved map can be calculated. This, in turn, can again be averaged until convergence has been reached and the phases no longer change. In addition, the back-transformed map can be used to compute phases just beyond the extremity of the resolution of the terms used in the original map. The resultant amplitudes will not be zero because the map had been modified by averaging and solvent flattening. Thus, phases can be gradually extended and improved, starting from a very low resolution approximation to the molecular structure. This procedure was first implemented in reciprocal space (Rossmann & Blow, 1963; Main, 1967; Crowther, 1969) and then, more recently, in real space (Bricogne, 1974, 1976; Johnson, 1978; Jones, 1992; Rossmann *et al.*, 1992). More recently still, there has been an attempt to reproduce the very successful real-space procedure in reciprocal space (Tong & Rossmann, 1995).

Early examples of such a procedure for phase improvement are the structure determinations of deoxyhaemoglobin (Muirhead *et al.*, 1967), α-chymotrypsin (Matthews *et al.*, 1967), lobster glyceraldehyde-3-phosphate dehydrogenase (Buehner *et al.*, 1974), hexokinase (Fletterick & Steitz, 1976), tobacco mosaic virus disk protein (Champness *et al.*, 1976; Bloomer *et al.*, 1978), the influenza virus haemagglutinin spike (Wilson *et al.*, 1981), tomato bushy stunt virus (Harrison *et al.*, 1978) and southern bean mosaic virus (Abad-Zapatero *et al.*, 1980). Early examples of phase extension, using real-space electron-density averaging, were the study of glyceraldehyde-3-phosphate dehydrogenase (Argos *et al.*, 1975), satellite tobacco necrosis virus (Nordman, 1980), haemocyanin (Gaykema *et al.*, 1984), human rhinovirus 14 (Rossmann *et al.*, 1985) and poliovirus (Hogle *et al.*, 1985). Since then, this method has been used in numerous virus structure determinations, with the phase extension being initiated from ever lower resolution.

A once-popular computer program for real-space averaging was written by Gerard Bricogne (1976). Another program has been described by Johnson (1978). Both programs were based on a double-sorting procedure. Bricogne (1976) had suggested that, with interpolation between grid points using linear polynomials, it was necessary to sample electron density at grid intervals finer than one-sixth of the resolution limit of the Fourier terms that were used in calculating the map. With the availability of more computer memory, it was possible to store much of the electron density, thus avoiding time-consuming sorting operations (Hogle *et al.*, 1985; Luo *et al.*, 1989). Simultaneously, the storage requirements could be drastically reduced by using interpolation with quadratic polynomials. While the latter required a little extra computation time, this was far less than what would have been needed for sorting. Furthermore, it was found that Bricogne's estimate for the fineness of the map storage grid was too pessimistic, even for linear interpolation, which works well to about 1/2.5 of the resolution limit of the map.

In addition to changes in strategy brought about by computers with much larger memories, experience has been gained in program requirements for real-space averaging for phase determination (Dodson *et al.*, 1992). Here we give a general procedure for electron-density averaging.

13.4.4. The *p*- and *h*-cells

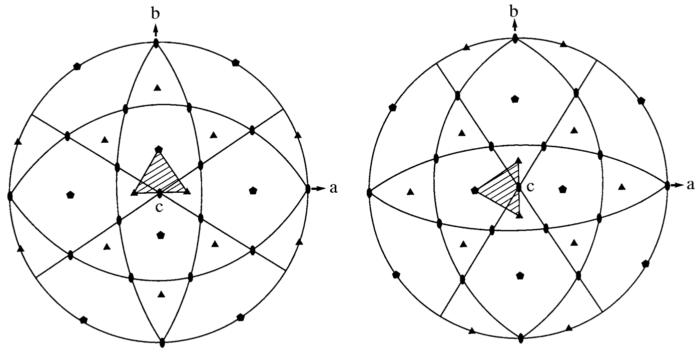
It is useful to define two types of unit cells.

(1) The 'p-cell' is the unit cell of the unknown crystal structure and is associated with fractional coordinates $\mathbf{y}$ and unit-cell vectors $\mathbf{a}_p$, $\mathbf{b}_p$, $\mathbf{c}_p$.

(2) The 'h-cell' is the unit cell with respect to which the noncrystallographic axes of the molecule (or particle) are to be defined in a standard orientation and is associated with fractional coordinates $\mathbf{x}$ and unit-cell vectors $\mathbf{a}_h$, $\mathbf{b}_h$, $\mathbf{c}_h$.

Since the averaged molecule is to be placed into all crystallographically related positions in the p-cell, it is essential to know the envelope that encloses a single molecule. Care must be taken that the envelopes from neighbouring molecules in the p-cell do not overlap. The remaining space between the limits of the envelopes of the variously placed molecules in the p-cell can be taken to be solvent and, hence, flattened, a useful physical assumption for helping phase determination.

The h-cell must be chosen to be at least as large as the largest dimension of the molecule. In general, it is convenient to define the h-cell with $a_h = b_h = c_h$ and $\alpha = \beta = \gamma = 90^\circ$, while placing the molecular centre at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. For example, if the molecule is a viral particle with icosahedral symmetry, the standard orientation can be defined by placing the twofold axes to correspond to the h-cell unit-cell axes, a procedure which can be done in one of two ways (Fig. 13.4.4.1). It will be necessary to know how the molecule (or particle) in the h-cell is related to the 'reference' molecule in the p-cell. The known p-cell crystallographic symmetry then permits the complete construction of the p-cell structure from whatever is the current h-cell electron-density representation of the molecule.



(*a*) (*b*)

Figure 13.4.4.1
Stereographic projections showing alternative definitions of the 'standard orientation' of an icosahedron in the *h*-cell. Icosahedral axes are placed parallel to the cell axes. Limits of a noncrystallographic asymmetric unit are shaded, representing 1/60th of the volume of an object with icosahedral symmetry. [Reproduced with permission from Rossmann *et al.* (1992).]

The *h*-cell is used to represent the density of a molecule in the standard orientation obtained by averaging all the noncrystallographic units in the *p*-cell. While density within a specific molecule will tend to be reinforced by the averaging procedure, the density outside the molecular boundaries will tend to be diminished. Thus, by averaging into the *h*-cell, the molecular envelope is revealed automatically. Indeed, the greater the NCS, the greater the clarity of the molecular boundary. Hence, the averaged molecule in the *h*-cell can be used to define a molecular mask in the *p*-cell automatically.

Averaging into the *h*-cell is also useful for displaying the molecule in a standard orientation (*i.e.* obtaining the electron-density distribution on skew planes). Thus, it is possible to display the molecule, for instance, with sections perpendicular to a molecular twofold axis, and to position the molecular symmetry axes accurately. From this, it is then easy to define the limits of the molecular asymmetric unit (Fig. 13.4.4.1). Hence, it is possible to save a great deal of computing time by evaluating the electron density in the *h*-cell only at those grid points within and immediately surrounding the noncrystallographic asymmetric unit.

13.4.5. Combining crystallographic and noncrystallographic symmetry

Transformations will now be described which relate noncrystallographically related positions distributed among several fragmented copies of the molecule in the asymmetric unit of the *p*-cell and between the *p*-cell and the *h*-cell.

13.4.5.1. General considerations

Let $\mathbf{Y}$ and $\mathbf{X}$ be position vectors in a Cartesian coordinate system whose components have dimensions of length, in the *p*- and *h*-cells, which utilize the same origin as the fractional coordinates, $\mathbf{y}$ and $\mathbf{x}$, respectively. Let $[\beta_p]$ and $[\alpha_h]$ be 'orthogonalization' and 'de-orthogonalization' matrices in the *p*- and *h*-cells, respectively (Rossmann & Blow, 1962). Then

$$\begin{array}{lll} \mathbf{Y} = [\beta_p]\mathbf{y} & \text{and} & \mathbf{x} = [\alpha_h]\mathbf{X}, \\ [\alpha_p] = [\beta_p]^{-1} & \text{and} & [\alpha_h] = [\beta_h]^{-1}. \end{array} \qquad (13.4.5.1)$$

Thus, for instance, $[\alpha_h]$ denotes a matrix that transforms a Cartesian set of unit vectors to fractional distances along the unit-cell vectors $\mathbf{a}_h$, $\mathbf{b}_h$, $\mathbf{c}_h$.

Let the Cartesian coordinates $\mathbf{Y}$ and $\mathbf{X}$ be related by the rotation matrix $[\omega]$ and the translation vector $\mathbf{D}$ such that

$$\mathbf{X} = [\omega]\mathbf{Y} + \mathbf{D}. \qquad (13.4.5.2)$$

If the molecules are to be averaged among different unit cells, then each *p*-cell must be related to the standard *h*-cell orientation by a different $[\omega]$ and $\mathbf{D}$. Then, from (13.4.5.1) and (13.4.5.2)

$$\mathbf{X} = [\omega][\beta_p]\mathbf{y} + \mathbf{D}. \qquad (13.4.5.3)$$

Now, if $[\omega]$ represents the rotational relationship between the 'reference' molecule, $m = 1$, in the *p*-cell with respect to the *h*-cell, then from (13.4.5.3)

$$\mathbf{X} = [\omega][\beta_p]\mathbf{y}_{m=1} + \mathbf{D},$$

where $\mathbf{y}_m$ refers to the fractional coordinates of the *m*th molecule in the *p*-cell.

Assuming there is only one molecule per asymmetric unit in the *p*-cell, let the *m*th molecule in the *p*-cell be related to the reference molecule by the crystallographic rotation $[\mathrm{T}_m]$ and translational operators $\mathbf{t}_m$, such that

$$\mathbf{y}_m = [\mathrm{T}_m]\mathbf{y}_{m=1} + \mathbf{t}_m. \qquad (13.4.5.4)$$

For convenience, all translational components will initially be neglected in the further derivations below, but they will be reintroduced in the final stages. Hence, from (13.4.5.3) and (13.4.5.4)

$$\mathbf{X} = \{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_m. \qquad (13.4.5.5)$$

Further, if $\mathbf{X}_n$ refers to the *n*th subunit within the molecule in the *h*-cell, and similarly if $\mathbf{y}_{m,n}$ refers to the *n*th subunit within the *m*th molecule of the *p*-cell, then from (13.4.5.5)

$$\mathbf{X}_n = \{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_{m,n}. \qquad (13.4.5.6)$$

Finally, the rotation matrix $[\mathrm{R}_n]$ is used to define the relationship among the N ($N = 2$ for a dimer, 4 for a 222 tetramer, 60 for an icosahedral virus *etc.*) noncrystallographic asymmetric units of the molecule within the *h*-cell. Then

$$\mathbf{X}_n = [\mathrm{R}_n]\mathbf{X}_{n=1}. \qquad (13.4.5.7)$$

13.4.5.2. Averaging with the p-cell

Consider averaging the density at N noncrystallographically related points in the *p*-cell and replacing that density into the *p*-cell. By substituting for $\mathbf{X}_n$ and $\mathbf{X}_{n=1}$ in (13.4.5.7) and using (13.4.5.6),

$$\{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_{m,n} = [\mathrm{R}_n]\{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_{m,n=1},$$

or

$$\mathbf{y}_{m,n} = \{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}^{-1} \times [\mathrm{R}_n]\{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_{m,n=1}. \qquad (13.4.5.8)$$

Now set

$$\begin{aligned} [\mathrm{E}_{m,n}] &= \{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}^{-1}[\mathrm{R}_n]\{[\omega][\beta_p][\mathrm{T}_m^{-1}]\} \\ &= [\mathrm{T}_m][\alpha_p][\omega^{-1}][\mathrm{R}_n][\omega][\beta_p][\mathrm{T}_m^{-1}], \end{aligned} \qquad (13.4.5.9)$$

giving

$$\mathbf{y}_{m,n} = [\mathrm{E}_{m,n}]\mathbf{y}_{m,n=1} + \mathbf{e}_{m,n}, \qquad (13.4.5.10)$$

where $\mathbf{e}_{m,n}$ is the corresponding translational element. Note that multiplication by $[\mathrm{E}_{m,n}]$ thus corresponds to the following sequence of transformations: (1) placing all the crystallographically related subunits into the reference orientation with $[\mathrm{T}_m^{-1}]$; (2) ‘orthogonalizing’ the coordinates with $[\beta_p]$; (3) rotating the coordinates into the *h*-cell with $[\omega]$; (4) rotating from the reference subunit of the molecule of the *h*-cell with $[\mathrm{R}_n]$; (5) rotating these back into the *p*-cell with $[\omega^{-1}]$; (6) ‘de-orthogonalizing’ in the *p*-cell with $[\alpha_p]$; and (7) placing these back into each of the *M* crystallographic asymmetric units of the *p*-cell with $[\mathrm{T}_m]$.

The translational elements, $\mathbf{e}_{m,n}$, can now be evaluated. Let $\mathbf{s}_{p,m}$ be the fractional coordinates of the centre (or some arbitrary position) of the *m*th molecule in the *p*-cell; hence, $\mathbf{s}_{p,m=1}$ denotes the molecular centre position of the reference molecule in the *p*-cell. If $\mathbf{s}_{p,m}$ is at the intersection of the molecular rotation axes, then it will be the same for all *n* molecular asymmetric units. Therefore, it follows from (13.4.5.10) that

$$\mathbf{e}_{m,n} = \mathbf{s}_{p,m} - [\mathrm{E}_{m,n}]\mathbf{s}_{p,m=1}, \qquad (13.4.5.11a)$$

or

$$\mathbf{y}_{m,n} = [\mathrm{E}_{m,n}]\mathbf{y}_{m,n=1} + (\mathbf{s}_{p,m} - [\mathrm{E}_{m,n}]\mathbf{s}_{p,m=1}). \qquad (13.4.5.11b)$$

Equation (13.4.5.11*b*) can be used to find all the *N* noncrystallographic asymmetric units within the crystallographic asymmetric unit of the *p*-cell. Thus, this is the essential equation for averaging the density in the *p*-cell and replacing it into the *p*-cell.

13.4.5.3. *Averaging the p-cell and placing the results into the h-cell*

Consider averaging the density at *N* noncrystallographically related points in the *p*-cell and placing that result into the *h*-cell. From (13.4.5.7), multiplying by $[\alpha_h]$,

$$[\alpha_h][\mathbf{X}_{n=1}] = [\alpha_h][\mathrm{R}_n^{-1}]\mathbf{X}_n.$$

From (13.4.5.1) and (13.4.5.6),

$$\mathbf{x}_{n=1} = [\alpha_h][\mathrm{R}_n^{-1}]\{[\omega][\beta_p][\mathrm{T}_m^{-1}]\}\mathbf{y}_{m,n}. \qquad (13.4.5.12)$$

Since it is only necessary to place the reference molecule of the *p*-cell into the *h*-cell, it is sufficient to consider the case when $m = 1$, in which case $[\mathrm{T}_m^{-1}]$ is the identity matrix [I]. It then follows, by inversion, that

$$\begin{aligned}\mathbf{y}_{m=1,n} &= \{[\omega][\beta_p]\}^{-1}[\mathrm{R}_n][\beta_h]\mathbf{x}_{n=1}\\ &= [\alpha_p][\omega^{-1}][\mathrm{R}_n][\beta_h]\mathbf{x}_{n=1},\end{aligned}$$

which corresponds to: (1) ‘orthogonalizing’ the *h*-cell fractional coordinates with $[\beta_h]$; (2) rotating into the *n*th noncrystallographic unit within the molecule using $[\mathrm{R}_n]$; (3) rotating into the *p*-cell with $[\omega^{-1}]$; and (4) ‘de-orthogonalizing’ into fractional *p*-cell coordinates with $[\alpha_p]$.

Now, if $\mathbf{s}_h$ is the molecular centre in the *h*-cell (usually $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$), then

$$\mathbf{y}_{m=1,n} = [\mathrm{E}'_{m=1,n}]\mathbf{x} + (\mathbf{s}_{p,m=1} - [\mathrm{E}'_{m=1,n}]\mathbf{s}_h),$$

and

$$[\mathrm{E}'_{m=1,n}] = [\alpha_p][\omega^{-1}][\mathrm{R}_n][\beta_h]. \qquad (13.4.5.13)$$

Equation (13.4.5.13) determines the position of the *N* noncrystallographically related points $\mathbf{y}_{m=1,n}$ in the *p*-cell whose average value is to be placed at $\mathbf{x}$ in the *h*-cell.

13.4.6. Determining the molecular envelope

Various techniques are available for determining the molecular envelope within which density can be averaged and outside of which the solvent can be flattened.

(1) By assumption of a simple geometric shape, such as a sphere. This is frequently used for icosahedral viruses.

(2) By manual inspection of a poor electron-density map which, nevertheless, gives some guidance as to the molecular boundaries. A variety of interactive graphical programs are available to help define the molecular boundary.

(3) By use of a homologous structure or other information, such as a cryo-electron-microscopy (cryo-EM) reconstruction at low resolution. The information about a homologous structure may be either in the form of an electron-density grid or, often more conveniently, as an atomic model.

(4) By inspection of an averaged map which should have weaker density beyond the limits of the molecular boundary where the NCS is no longer true.

Procedures (2) and (3) are advisable when the NCS redundancy is low. Procedure (4) works well when the NCS redundancy is four or higher. The crystallographic asymmetric unit is likely to contain bits and pieces of molecules centred at various positions in the unit cell and neighbouring unit cells. Therefore, it is necessary to associate each grid point within the *p*-cell crystallographic asymmetric unit to a specific molecular centre or to solvent.

If the molecular-boundary assignments are to be made automatically, then the following procedure can be used. The number, *M*, of such molecules can be estimated by generating all centres, derived from the given position of the centre for the reference molecule, $\mathbf{s}_{p,n=1}$, and then determining whether a molecule of radius R_{out} would impinge on the crystallographic asymmetric unit within the defined boundaries. Here, R_{out} is a liberal estimate of the molecular radius. The corresponding rotation matrices $[\mathrm{E}_{m,n}]$ and translation vectors $\mathbf{e}_{m,n}$ can then be computed from (13.4.5.9) and (13.4.5.11*a*).

Any grid point whose distance from all *M* centres is greater than R_{out} can immediately be designated as being in the solvent region. For other grid points, it is necessary to examine the corresponding *h*-cell density. From (13.4.5.12), it follows that (setting $n = 1$)

$$\mathbf{x} = [\mathrm{E}''_{m,n=1}]\mathbf{y}_m + (\mathbf{s}_h - [\mathrm{E}''_{m,n=1}]\mathbf{s}_{p,m}),$$

where

$$[\mathrm{E}''_{m,n=1}] = [\alpha_h][\mathrm{R}_n^{-1}][\omega][\beta_p][\mathrm{T}_m^{-1}] \qquad (13.4.6.1)$$

(*n* can be set to 1, since the *h*-cell presumably contains an averaged molecular electron density, in which case it does not matter which molecular asymmetric unit is referenced). Thus, (13.4.6.1) can be used to determine the electron density at $\mathbf{y}_m$ by inspecting the corresponding interpolated density, $\rho(\mathbf{x})$, at $\mathbf{x}$ in the *h*-cell. Transfer of the electron density, $\rho(\mathbf{x})$, from the *h*-cell to the *p*-cell using (13.4.6.1) is often useful to obtain an initial structure. However, to determine a suitable mask, it is useful to evaluate a modified electron density, $\langle\rho(\mathbf{x})\rangle$, (see below) for the grid points immediately around $\mathbf{x}$ in the *h*-cell.

A variable parameter ‘CRIT’ can be specified to establish the distribution of grid points that are within the molecular envelope. When the modified electron density, $\langle\rho(\mathbf{x})\rangle$, is less than CRIT, the corresponding grid point at $\mathbf{y}$ is assumed to be in solvent. Otherwise, when $\langle\rho(\mathbf{x})\rangle$ exceeds CRIT, the grid point at $\mathbf{y}$ is assigned to that molecule which has the largest $\langle\rho(\mathbf{x})\rangle$. If the percentage of grid points which might be assigned to more than one molecule is large (say, greater than 1% of the total number of grid points), it probably signifies that the value of CRIT is too low, that the molecular boundary is far from clear, or that the

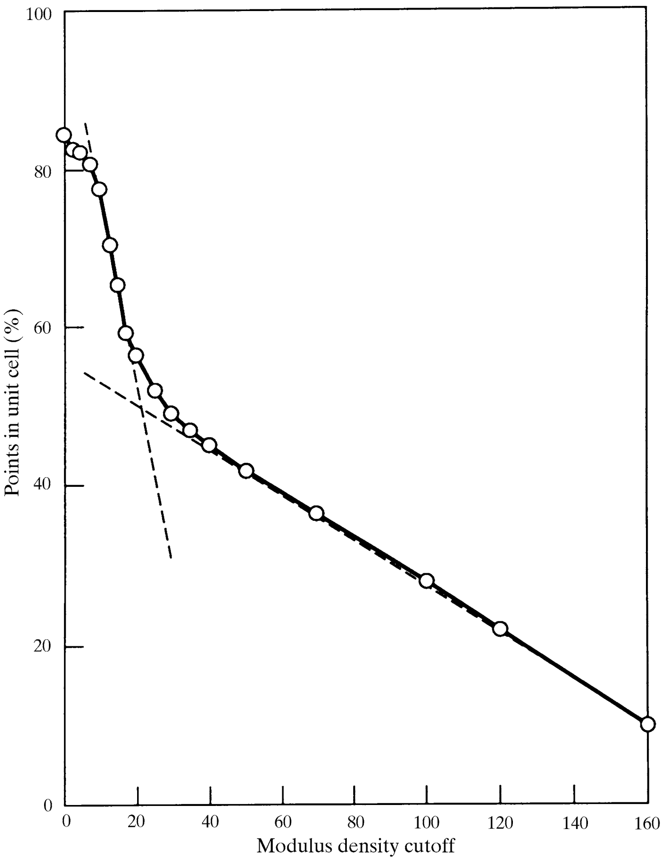


Figure 13.4.6.1
The volume of the molecular mask expressed as a percentage of the volume of the p-cell asymmetric unit, as determined by the density cutoff in the h-cell. When the modulus of the density cutoff is decreased to less than the mean smeared electron density within the protein, the mask volume increases rapidly. Intersection of the tangents suggests the most appropriate density cutoff value for mask generation. [Reproduced with permission from McKenna, Xia, Willingmann, Ilag & Rossmann (1992).]

function used to define $\langle\rho(\mathbf{x})\rangle$ was badly chosen (Fig. 13.4.6.1). Grid points outside the molecular envelope can be set to the average solvent density.

An essential criterion for the molecular envelope is that it obeys the noncrystallographic point-group symmetry. If the original h-cell electron density already possesses the molecular symmetry (*e.g.* icosahedral 532, 222 *etc.*), then the p-cell mask should also have that symmetry. However, if the mask boundaries were chosen manually, masks from different molecular centres might be in conflict and have local errors in the correct molecular symmetry. Such errors can be corrected by reimposing the noncrystallographic point-group symmetry on the p-cell mask. This can be conveniently achieved by setting the density at each grid point that was considered within the molecular envelope to a value of 100, and all other grid points to a density of zero. If the resultant density is averaged using the same routine as is used for averaging the actual electron density of the molecule, then the average density will remain 100 if the interpolated density is 100 at all noncrystallographically related points. However, if the original grid point is near the edge of the mask, finding the density at symmetry-related points may involve interpolation between density at level 100 and at level 0, giving an averaged density of less than 100. Hence, any grid point whose averaged density is below some criterion should be attributed to solvent.

Other improvements to mask generation were discussed by Rossmann *et al.* (1992). In any event, the molecular-envelope definition should be periodically re-examined after a suitable number of electron-density-averaging cycles.

Table 13.4.7.1
Mean root-mean-square scatter between noncrystallographically related points

Example taken from φX174 structure determination. $\langle\rho_8\rangle$ is proportional to the mean density (e Å^{-3}) based on eight-point interpolation; n is number of grid points with $\langle\rho_8\rangle$ in a given range; $\langle\sigma(\rho_8)\rangle$ is the root-mean-square deviation from ρ_8 among noncrystallographic asymmetric points averaged over all points in the mask.

	Density derived from an electron microscopy image at 25 Å resolution		Density derived from a 3.3 Å crystal structure

13.4.7. Finding the averaged density

Electron density can be averaged (1) among the N NCS-related molecules in the p-cell (the real crystal unit cell), thus creating a new and improved map of the p-cell; (2) among the N NCS-related molecules in the p-cell and placing the results into a standard orientation in the h-cell; or (3) among the N NCS-related molecules in different unit cells and placing the results back into the original different unit cells or into a standard h-cell. Before averaging commences, the $M \times N$ matrices $[\mathrm{E}_{m,n}]$ and translation vectors $\mathbf{e}_{m,n}$ must be evaluated [see (13.4.5.9) and (13.4.5.11*a*)]. Here, N is the noncrystallographic redundancy and M is the number of molecules that impinge on the crystallographic asymmetric unit of the p-cell. Associated with each grid point in the p-cell asymmetric unit will be (1) the value of m designating which molecular centre is to be associated with that grid point (a special value of m is for solvent) and (2) the p-cell electron density at that point.

The grid points within the asymmetric unit are then examined one at a time. If the grid point is within the mask, it is averaged among the N noncrystallographically related equivalent positions belonging to molecule m. If the grid point is solvent, the density can be set to the average solvent density.

The N noncrystallographically equivalent non-integral grid points can be computed from (13.4.5.11*a*). Some of these will lie outside the crystallographic asymmetric unit. These will, therefore, have to be operated on by unit-cell translations and crystallographic symmetry operations to bring them back into the asymmetric unit before the corresponding interpolated density can be calculated.

Averaging into the h-cell can be done by a procedure similar to averaging in the p-cell, except that the rotation and translation matrices are given by (13.4.5.13). Furthermore, no mask is required as all the averaging into the h-cell (from p-cell electron

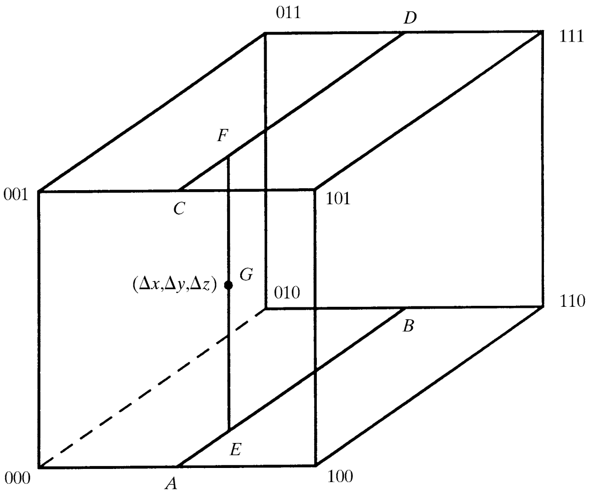

Figure 13.4.8.1
Interpolation box for finding the approximate electron density at $G(\Delta x, \Delta y, \Delta z)$, given the eight densities at the corners of the box. The interpolated value can be built up by first using interpolations to determine the densities at A, B, C and D. A second linear interpolation then determines the density at E (from densities at A and B) and at F (from densities at C and D). The third linear interpolation determines the density at G from the densities at E and F. [Reproduced with permission from Rossmann *et al.* (1992).]

density) can be done with respect to the reference molecule centred at $\mathbf{s}_{p,\,m=1}$ in the p-cell. Each grid point is taken in turn in the h-cell. The electron density at any grid point that is further away from $\mathbf{s}_{\rm h}$ than from $R_{\rm out}$ is set to zero. Other grid-point positions are expanded into the N equivalent positions in the p-cell surrounding $\mathbf{s}_{p,\,m=1}$. The interpolated density is then found, averaged over the N equivalent positions, and stored at the original h-cell grid point in successive sections, in the same way as in the p-cell averaging. As in averaging within the p-cell, a record is kept of $\langle\sigma(\rho)\rangle$ as a function of $\langle\rho(\mathbf{x})\rangle$ (Table 13.4.7.1). In general, the local NCS is valid only within the molecule. Hence, the h-cell density will show the molecular envelope and can be used to recompute an improved p-cell density mask. The rate of build up of signal within the molecule should be roughly proportional to N, while the rate outside the molecule should be proportional to about $N^{1/2}$.

13.4.8. Interpolation

Some thought must go into defining the size of the grid interval. Shannon's sampling theorem shows that the grid interval must never be greater than half the limiting resolution of the data. Thus, for instance, if the limiting resolution is 3 Å, the grid intervals must be smaller than 1.5 Å. Clearly, the finer the grid interval, the more accurate the interpolated density, but the computing time will increase with the inverse cube of the size of the grid step. Similarly, if the grid interval is fine, less care and fewer points can be used for interpolation, thus balancing the effect of the finer grid in terms of computing time. In practice, it has been found that an eight-point interpolation (as described below) can be used, provided the grid interval is less than 1/2.5 of the resolution (Rossmann *et al.*, 1992). Other interpolation schemes have also been used (*e.g.* Bricogne, 1976; Nordman, 1980; Hogle *et al.*, 1985; Bolin *et al.*, 1993).

A straightforward 'linear' interpolation can be discussed with reference to Fig. 13.4.8.1 (in mathematical literature, this is called a trilinear approximation or a tensor product of three one-dimensional linear interpolants). Let G be the position at which the density is to be interpolated, and let this point have the fractional grid coordinates Δx, Δy, Δz within the box of surrounding grid points. Let 000 be the point at $\Delta x = 0$, $\Delta y = 0$, $\Delta z = 0$. Other grid points will then be at 100, 010, 001 *etc.*, with the point diagonally opposite the origin at 111.

The density at A (between 000 and 100) can then be approximated as the value of the linear interpolant of ρ_{000} and ρ_{100}:

$$\rho(A) \cong \rho_A = \rho_{000} + (\rho_{100} - \rho_{000})\Delta x.$$

Similar expressions for $\rho(B)$, $\rho(C)$ and $\rho(D)$ can also be written. Then, it is possible to calculate an approximate density at E from

$$\rho(E) \cong \rho_E = \rho_A + (\rho_B - \rho_A)\Delta y,$$

with a similar expression for $\rho(F)$. Finally, the interpolated density at G between E and F is given by

$$\rho(G) \cong \rho_G = \rho_E + (\rho_F - \rho_E)\Delta z.$$

Putting all these together, it is easy to show that

$$\begin{aligned}\rho_G = \rho_{000} &+ \Delta x(\rho_{100} - \rho_{000}) + \Delta y(\rho_{010} - \rho_{000}) + \Delta z(\rho_{001} - \rho_{000})\\ &+ \Delta x\Delta y(\rho_{000} + \rho_{110} - \rho_{100} - \rho_{010})\\ &+ \Delta y\Delta z(\rho_{000} + \rho_{011} - \rho_{010} - \rho_{001})\\ &+ \Delta z\Delta x(\rho_{000} + \rho_{101} - \rho_{001} - \rho_{100})\\ &+ \Delta x\Delta y\Delta z(\rho_{100} + \rho_{010} + \rho_{001} + \rho_{111} - \rho_{000} - \rho_{101}\\ &- \rho_{011} - \rho_{110}).\end{aligned}$$

13.4.9. Combining different crystal forms

Frequently, a molecule crystallizes in a variety of different crystal forms [*e.g.* hexokinase (Fletterick & Steitz, 1976), the influenza virus neuraminidase spike (Varghese *et al.*, 1983), the histocompatibility antigen HLA (Bjorkman *et al.*, 1987) and the CD4 receptor (Wang *et al.*, 1990)]. It is then advantageous to average between the different crystal forms. This can be achieved by averaging each crystal form independently into a standard orientation in the h-cell (if the redundancy is $N = 1$ for a given crystal form, then this simply amounts to producing a skewed representation of the p-cell in the h-cell environment). The different results, now all in the same h-cell orientation, can be averaged. However, care must be taken to put equal weight on each molecular copy. If the ith cell contains N_i noncrystallographic copies, then the average of the densities, $\rho_i(\mathbf{x})$ $(i = 1, 2, \ldots, I)$, is

$$\sum_i N_i\rho_i(\mathbf{x}) \Big/ \sum_i N_i$$

at each grid point, $\mathbf{x}$, in the h-cell. Additional weights can be added to account for the subjective assessment of the quality of the electron densities in the different crystal cells.

With the h-cell density improved by averaging among different crystal forms, it can now be replaced into the different p-cells. These p-cells can then be back-transformed in the usual manner to obtain a better set of phases. These, in turn, can be associated with the observed structure amplitudes for each p-cell structure, and the cycle can be repeated.

13.4.10. Phase extension and refinement of the NCS parameters

Fourier back-transformation of the modified (averaged and solvent-flattened) map leads to poor phase information immediately outside the previously used resolution limit. If no density modification had been made, the Fourier transform would have yielded exactly the same structure factors as had been used for the original map. However, the modifications result in small structure amplitudes just beyond the previous resolution limit. The resultant phases can then be used in combination with the observed amplitudes in the next map calculation, thus extending the limit of resolution.

If the cell edge of an approximately cubic unit cell is a, and the approximate radius of the molecule is $\mathcal{R}$ (therefore, $\mathcal{R} < a$), then the first node of a spherical diffraction function will occur when $H\mathcal{R} = 0.7$, where H is the length of the reciprocal-lattice vector between the closest previously known structure factor and the structure factor just outside the resolution limit. Let $H = n(1/a)$, and let it be assumed that the diffraction-function amplitude is negligible when $H\mathcal{R} > 0.7$. Thus, for successful extension, $n = a/\mathcal{R}$. In general, that means that phase extension should be less than two reciprocal-lattice units in one step.

As phase extension proceeds, the accuracy of the NCS elements and the boundaries of the envelope must be constantly improved and updated to match the improved resolution. Arnold & Rossmann (1986, 1988) discussed phase error as a function of error in the NCS definition and applied rigid-body least-squares refinement for refining particle position and orientation of human rhinovirus 14. The 'climb' procedure has been found especially useful (Muckelbauer *et al.*, 1995). This depends upon searching one at a time for the parameters (rotational and translational) that minimize the near r.m.s. deviation of the individual densities to the resultant averaged densities.

Improvement of the NCS parameters is dependent upon an accurate knowledge of the cell dimensions. In the absence of such knowledge, the rotational NCS relationship cannot be accurate, since elastic distortion will result, leading to very poor averaged density. This was the case in the early determination of southern bean mosaic virus (Abad-Zapatero *et al.*, 1980), where the structure solution was probably delayed at least one year due to a lack of accurate cell dimensions.

Another aspect to phase extension is the progressive decrease in or quality of observed structure amplitudes. The observed amplitudes can be augmented with the calculated values obtained by Fourier back-transformation of the averaged map. However, clearly, as the number of calculated values increases in proportion to the number of observed values, the rate of convergence decreases. In the limit, when there are no available $F_{\rm obs}$ values, averaging a map based on $F_{\rm calc}$ values will not alter it, and, thus, convergence stops entirely.

13.4.11. Convergence

Iterations consist of averaging, Fourier inversion of the average map, recombination of observed structure-factor amplitudes with calculated phases, and recalculation of a new electron-density map. Presumably, each new map is an improvement of the previous map as a consequence of using the improved phases resulting from the map-averaging procedure. However, after five or ten cycles, the procedure has usually converged so that each new map is essentially the same as the previous map. Convergence can be usefully measured by computing the correlation coefficient (*CC*) and *R* factor (*R*) between calculated ($F_{\rm calc}$) and observed ($F_{\rm obs}$) structure-factor amplitudes as a function of resolution (Fig. 13.4.11.1). These factors are defined as

$$CC = \frac{\sum_h(\langle F_{\rm obs}\rangle - F_{\rm obs})(\langle F_{\rm calc}\rangle - F_{\rm calc})}{\left[\sum_h(\langle F_{\rm obs}\rangle - F_{\rm obs})^2(\langle F_{\rm calc}\rangle - F_{\rm calc})^2\right]^{1/2}},$$

$$R = 100 \times \sum\left|\left(|F_{\rm obs}| - |F_{\rm calc}|\right)\right| \Big/ \sum|F_{\rm obs}|.$$

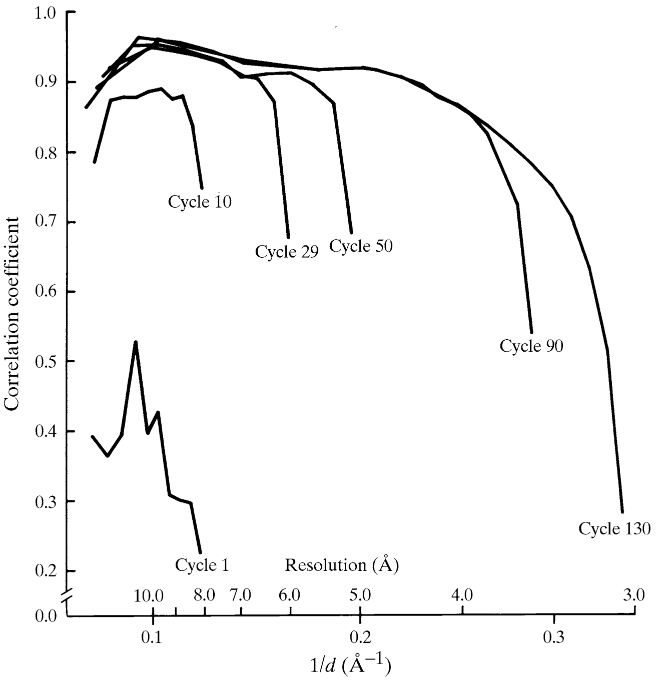

Figure 13.4.11.1

Plot of a correlation coefficient as the phases were extended from 8 to 3 Å resolution in the structure determination of Mengo virus. [Reproduced with permission from Luo *et al.* (1989).]

Because of the lack of information immediately outside the resolution limit, these factors must necessarily be poor in the outermost resolution shell. Nevertheless, the outermost resolution shell will be the most sensitive to phase improvement as these structure factors will be the furthest from their correct values at the start of a set of iterations after a resolution extension.

Convergence of *CC* and *R* does not, however, necessarily mean that phases are no longer changing from cycle to cycle. Usually, the small-amplitude structure factors keep changing long after convergence appears to have been reached (unpublished results). However, the small-amplitude structure factors make very little difference to the electron-density maps.

The rate of convergence can be improved by suitably weighting coefficients in the computation of the next electron-density map. It can be useful to reduce the weight of those structure factors where the difference between observed and calculated amplitudes is larger than the average difference, as, presumably, error in amplitude can also imply error in phase. Various weighting schemes are generally used (Sim, 1959; Rayment, 1983; Arnold *et al.*, 1987; Arnold & Rossmann, 1988).

As mentioned above, the rate of convergence can also be improved by inclusion of $F_{\rm calc}$ values when no $F_{\rm obs}$ values have been measured. However, care must be taken to use suitable weights to ensure that the $F_{\rm calc}$'s are not systematically larger or smaller than the $F_{\rm obs}$ values in the same resolution range.

Monitoring the *CC* or *R* factor for different classes of reflections (*e.g.* $h + k + l = 2n$ and $h + k + l = 2n + 1$) can be a good indicator of problems (Muckelbauer *et al.*, 1995), particularly in the presence of pseudo-symmetries. All classes of reflections should behave similarly.

The power (P) of the phase determination and, hence, the rate of convergence and error in the final phasing has been shown to be (Arnold & Rossmann, 1986) proportional to

$$P \propto (Nf)^{1/2}/[R(U/V)],$$

where N is the NCS redundancy, f is the fraction of observed reflections to those theoretically possible, R is a measure of error on the measured amplitudes (*e.g.* $R_{\rm merge}$) and U/V is the ratio of the volume of the density being averaged to the volume of the unit cell. Important implications of this relationship include that the phasing power is proportional to the square root of the NCS redundancy and that it is also dependent upon solvent content and diffraction-data quality and completeness.

13.4.12. *Ab initio* phasing starts

Some initial low-resolution model is required to initiate phasing at very low resolution. The use of cryo-EM reconstructions or available homologous structures is now quite usual. However, a phase determination using a sphere or hollow shell is also possible. In the case of a spherical virus, such an approximation is often very reasonable, as is evident when plotting the mean intensities at low resolution. These often show the anticipated distribution of a Fourier transform of a uniform sphere (Fig. 13.4.12.1). Thus, initiating phasing using a spherical model does require the prior determination of the average radius of the spherical virus. This can be done either by using an R-factor search (Tsao, Chapman & Rossmann, 1992) or by using low-angle X-ray scattering data (Chapman *et al.*, 1992). A minimal model would be to estimate the value of $F(000)$ on the same relative scale as the observed amplitudes. This structure factor must always have a positive value. Such a limited initial start was first explored by Rossmann & Blow (1963).

In surprisingly many cases (Valegård *et al.*, 1990; Chapman *et al.*, 1992; McKenna, Xia, Willingmann, Ilag, Krishnaswamy *et al.*, 1992; McKenna, Xia, Willingmann, Ilag & Rossmann, 1992; Tsao, Chapman & Rossmann, 1992; Tsao, Chapman, Wu *et al.*, 1992), it has been found that initiating phasing by using a very low resolution model results in a phase solution of the Babinet inverted structure ($\alpha \rightarrow \alpha + \pi$), where the desired density is negative instead of positive. Presumably, this is the result of phase convergence in a region where the assumed spherical transform is π out of step with reality. As long as this possibility is kept in mind with a watchful eye, such an inversion does not hamper good phase determination. In the case of phase extension, stepping too far in resolution can also lead to analogous problems (Arnold *et al.*, 1987).

Similar errors can occur due to lack of information on the correct enantiomorph in the initial phasing model. In some cases, where spherical envelopes are used and the distribution of NCS elements is also centric, there will be no decision on hand, and the phases will remain centric (Johnson *et al.*, 1975). However, in general, the enantiomorphic ambiguity (hand assignment) can be resolved by providing a model that has some asymmetry or by arbitrarily selecting the phase of a large-amplitude structure factor away from its centric value.

The progress of phase refinement away from false solutions has been the subject of 'post mortem' examinations (Valegård *et al.*, 1990; Chapman *et al.*, 1992; McKenna, Xia, Willingmann, Ilag, Krishnaswamy *et al.*, 1992; McKenna, Xia, Willingmann, Ilag & Rossmann, 1992; Tsao, Chapman & Rossmann, 1992; Tsao, Chapman, Wu *et al.*, 1992; Dokland *et al.*, 1998). The main lesson learned from these observations is that phase determination using NCS is amazingly powerful. Most initial errors in phasing gradually work themselves out with subsequent iterations and phase extension.

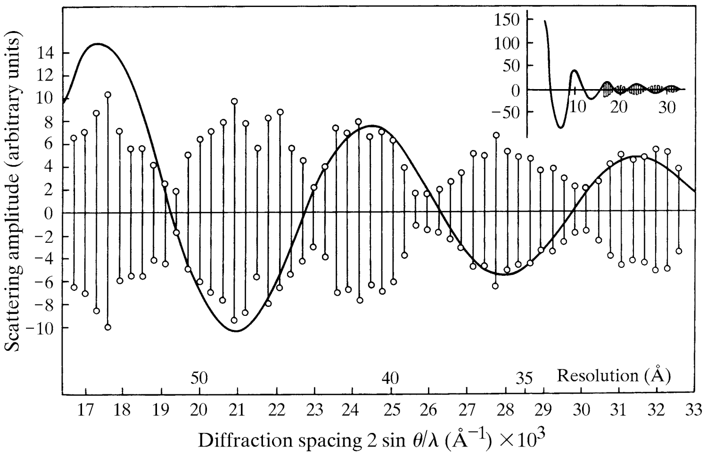

Figure 13.4.12.1
Structure amplitudes of the type II crystals of southern bean mosaic virus, averaged within shells of reciprocal space, shown in relation to the Fourier transform of a 284 Å diameter sphere. The inset shows the complete spherical transform from infinity to 30 Å resolution. [Reproduced with permission from Johnson *et al.* (1976). Copyright (1976) Academic Press.]

Perhaps the power of NCS phase determination should not be overly surprising. When phases are determined by multiple isomorphous replacement, the amount of data collected for the given molecular weight is $(N+1)$, where N is the number of derivatives and is usually 3 or 4. Similarly, for multiwavelength anomalous-dispersion data collection, there might be measurements at four different wavelengths, essentially giving $N = 8$ data points for each reflection. However, icosahedral virus determination frequently provides $N = 60$ data points for the equivalent resolution.

13.4.13. Recent salient examples in low-symmetry cases: multidomain averaging and systematic applications of multiple-crystal-form averaging

When averaging molecules that have segmental flexibility, it is essential to be able to define the extents of and noncrystallographic relationships among multiple segments which can flexibly reorient. No general protocol has been described for determining the minimum size or optimal number of segments to use in such cases. If the number of segments used for averaging is too small, then the NCS parameters cannot accurately superpose the entirety of the related segments. If too many segments are used for averaging, the segments may become too small for accurate determination of the NCS parameters. The use of too many segments may also become awkward and somewhat inefficient, since in some program systems the total number of maps that must be stored in a given cycle of averaging is proportional to the number of segments used for averaging. Comparison of atomic models for related segments that have been built or refined independently may provide convenient definitions of envelopes for averaging. In practice, a radius of 2 Å or more (depending upon the stage of structure solution and completeness and expected reliability of the model) may be added around the atoms used to define a molecular mask or envelope used in averaging. As with other averaging procedures, multidomain and multiple-crystal-form averaging approaches generally benefit from updating the molecular masks as structure determination progresses.

Often, a macromolecule can be crystallized in multiple crystal forms. Advances in crystallization technology leading to the frequent occurrence of multiple crystal forms, coupled with the availability of convenient programs, have led to increasing frequency of application of multiple-crystal-form averaging for structure solution.

Proteins, especially those containing more than one folded domain, often contain flexible hinges. As long as the boundaries of and noncrystallographic relationships among the related domains in multiple copies can be determined, then density averaging can be used to improve phasing. Programs such as *O* can be conveniently used to obtain the initial transformations necessary for correct superposition of related segments. NCS parameters can be refined using routines that either minimize the density differences among related copies or that perform rigid-body refinements of atomic models.

A number of experimental techniques have been described that may permit more widespread application of multiple-domain and multiple-crystal-form averaging. Freezing of macromolecular crystals to liquid-nitrogen temperatures has become a routine approach for enhancing the resolution and quality of macromolecular X-ray diffraction data. With most macromolecular crystals, there is a shrinkage of the 'frozen' unit cell relative to the lattice of the 'unfrozen' crystals. In many cases, significantly different cell dimensions can also be obtained by using different cryo-protective buffer and salt conditions. These variations can be exploited in a systematic fashion for phasing by electron-density averaging, so long as (1) the shrinkage relationships among the different crystals are not merely isotropic and (2) the boundaries and NCS parameters among related segments can be determined. Perutz (Perutz, 1946; Bragg & Perutz, 1952) recognized the potential utility of such shrinkage stages for crystallographic phasing in studies of haemoglobin crystals with varying degrees of hydration.

Recent examples of structure solutions involving multidomain and multiple-crystal-form averaging include studies of HIV reverse transcriptase (RT) (Ren *et al.*, 1995; Ding *et al.*, 1995). Studies of HIV RT by Stuart and coworkers involved multidomain and multiple-crystal-form averaging using different soaking solutions (Esnouf *et al.*, 1995; Ren *et al.*, 1995), in some cases with dramatically improved diffraction resolution. Arnold and coworkers have applied multidomain and multiple-crystal-form averaging to studies of HIV RT, including a systematic application of averaging electron density between 'frozen' and 'unfrozen' crystal forms (Ding *et al.*, 1995; Das *et al.*, 1996). Tong *et al.* (1997) recently described electron-density averaging among multiple closely related crystal forms of the human cytomegalovirus protease that were obtained by treatment of the crystals with different soaking buffers containing differing levels of precipitants, such as salt and polyethylene glycol.

13.4.14. Programs

This review hopefully covers most aspects encountered when employing electron-density averaging, yet the authors have drawn liberally from their own experience. There are now a large number of averaging programs and procedures available, some more suitable for structure determinations of proteins with low NCS redundancy and improper relationships (Jones, 1992) and others particularly suitable for high NCS redundancy, such as is encountered in the study of icosahedral viruses. For large structures, phase determination can be a very time-consuming computer operation. Therefore, attempts have been made to parallelize some programs (Cornea-Hasegan *et al.*, 1995), although this may lead to difficulties in exporting the programs to new and different computers.

Recently described program packages for symmetry averaging have been successfully applied to a number of cases. General program systems for averaging that are well suited to cases with high NCS include *ENVelope* (Rossmann *et al.*, 1992) and *GAP* (Jonathan Grimes and David Stuart, unpublished results); these same packages have also been used for multiple-crystal-form averaging and problems with low symmetry. A number of the program packages have been conveniently integrated with interactive computer-graphics programs such as *O* (Jones *et al.*, 1991) and most permit molecular-envelope definition by a number of possible approaches. *RAVE* and *MAVE* (Kleywegt & Jones, 1994), programs for graphics-assisted averaging within and between crystal forms, also come with an array of tools for flexible map handling and envelope definition (Kleywegt & Jones, 1996). The program systems *DMMULTI* (Cowtan & Main, 1993) and *MAGICSQUASH* (Schuller, 1996), which both derive from the program *SQUASH* (Zhang, 1993), can simultaneously apply real-space (symmetry averaging and solvent levelling with or without histogram matching) and reciprocal-space (phase refinement by the Sayre equation) constraints for phase improvement and extension. The advantage of adding phasing by the Sayre equation is greater at higher resolution, but appears to be significant in some cases, even at relatively low resolution (Cowtan & Main, 1993). *MAGICSQUASH* has been used to determine a number of structures which required multiple-domain and multiple-crystal-form averaging (Schuller, 1996). The *DEMON/ANGEL* package allows noncrystallographic averaging among multiple crystal forms together with solvent flattening and histogram matching (Vellieux *et al.*, 1995). Other versatile programs for electron-density averaging include *AVGSYS* (Bolin *et al.*, 1993) and *PHASES* (Furey & Swaminathan, 1990, 1997), both of which have features for facilitating definition and refinement of NCS parameters.

We are most grateful to Sharon Wilder and Cheryl Towell for extensive help in creating this manuscript. We are also grateful for decades of financial support by the National Science Foundation and the National Institutes of Health during the development of the techniques reported here.

Chapter 13.5. Molecular replacement with *MOLREP*

A. Vagin and A. Teplyakov

13.5.1. Introduction

Molecular replacement (MR) is one of the two principal methods of crystal structure determination (Rossmann, 1972). About two-thirds of the X-ray structures recently deposited in the Protein Data Bank (Berman *et al.*, 2000) have been determined by MR. With the rapid growth in the number of protein structures available as search models, the use of the method will increase even further in the future. Traditionally, MR has been implemented as a three-dimensional rotational search followed by a three-dimensional translational search. With recent advances in computing a combined six-dimensional search is becoming feasible; however, to date the most popular program packages for MR use various algorithms for a (3 + 3)-dimensional search. These include *AMoRe* (Navaza, 2001), *Phaser* (McCoy *et al.*, 2007) and the MR implementation in *CNS* (Brünger *et al.*, 1998; Chapter 18.6). Together with *MOLREP*, they cover over 95% of the structures solved by MR.

MOLREP is an automated program for molecular replacement that utilizes a number of original approaches to rotational and translational search and data preparation. *MOLREP* was initially developed (Vagin, 1989) as a fast and efficient alternative to the few existing program packages and has subsequently been enriched with new algorithms and adapted to various operating systems. *MOLREP* was originally part of the program suite *BLANC* (Vagin, 1982; Vagin *et al.*, 1998) and was later included in the *CCP*4 suite (Collaborative Computational Project, Number 4, 1994). *MOLREP* is a component of several MR pipelines, including *BALBES* (Long *et al.*, 2008), *MrBUMP* (Keegan & Winn, 2008) and the JCSG pipeline (Schwarzenbacher *et al.*, 2008), that utilize the entire PDB for fully automatic structure determination. Since the first publication describing the program (Vagin & Teplyakov, 1997) it has been cited over 3000 times. In this overview, we highlight unique features of the program, which include weighting of the X-ray data and search models, multi-copy search, fitting the model into electron density and structural superposition of two models by using the spherically averaged and phased translation function and rotation function.

13.5.2. Program operation

The philosophy behind *MOLREP* was to provide a tool such that most if not all of the tasks in MR could be performed automatically, or at least the optimal choice of parameters at each step of the process would be performed by the program. To make the program user-friendly, the interface was organized so that the user can run the program in a dialogue mode. The prompts appear as self-explanatory questions with a choice of possible answers and a list of keywords to define certain parameters. The batch mode using a command file or a command string is also available, as well as the *CCP4i* GUI.

MOLREP can perform a variety of tasks that require rotational and/or positional search: standard MR, multi-copy search, fitting a model into electron density, heavy-atom search and model superposition. The arsenal of rotation (RF) and translation (TF) functions includes self-RF, cross-RF, locked cross-RF, phased RF, full-symmetry TF, phased TF, spherically averaged phased TF and packing function (PF). The program is general for all space groups.

MR with *MOLREP* is not only fast and efficient but is also largely automatic. The minimum input provided by the user includes the X-ray data and the atomic model.

The input reflection file may be in *CCP*4 MTZ format, *BLANC* format or CIF format. An electron-density map or an electron-microscopy (EM) reconstruction (in *CCP*4 or *BLANC* format) may substitute for the structure factors. In this case, the map is converted to structure factors and phases. Crystal symmetry information is taken from the reflection file.

The input model is usually provided as an X-ray structure in the PDB format, but may also be an NMR ensemble. The ensemble is utilized either as a single entity (structure factors are calculated from the entire ensemble) or as individual members (MR is carried out for each structure). A set of homologous structures can be used in a similar way to the NMR ensemble. An electron-microscopy image or electron-density map can also substitute for the search model.

MOLREP can run with a minimum input using default parameters and parameters calculated from the input data. However, it may be useful to control the program through the use of a wide range of keywords to override the defaults. The keywords are described in the documentation supplied with the software.

The output of the program is a PDB file with the atomic model ready for refinement and a text file with details of the calculations. Additionally, an XML file suitable for communication between different programs in a pipeline is generated.

13.5.3. Preparation of the search model

The search model is automatically modified in various ways in order to try these variants for MR (Lebedev *et al.*, 2008). The options include (i) a polyalanine model, (ii) a model with modified atomic B factors increased proportionally to the atom accessibility and (iii) a model with the corrected amino-acid sequence according to the alignment of the search and target sequences. The alignment is carried out by the program when the target sequence is supplied. It takes into account the three-dimensional structure of the search model and weights the buried residues more than the surface residues. It also positions insertions and deletions away from the secondary-structure elements. Based on this alignment, certain atoms in the side chains and entire residues in the deletion regions are removed from the search model.

13.5.4. Preparation of the X-ray data

Proper treatment of the X-ray data may dramatically improve the results of MR and structure refinement. Several unique and conventional approaches for data scaling and correction have been implemented in *MOLREP*.

Anisotropic correction of the experimental data is applied when the X-ray intensity fall-off with resolution varies substantially with direction. The X-ray data are fitted to the isotropic Gaussian derived from the origin peak of the Patterson function (Rogers, 1965). The procedure is implemented in reciprocal space according to Blessing & Langs (1988).

Scaling of the observed and calculated structure factors is based on the scaling of the height and width of the corresponding Patterson origin peaks (Rogers, 1965; Blessing & Langs, 1988). This method is advantageous when only low-resolution data are available. In such a case, the estimation of the overall B factor ($B_{\rm over}$) from the Wilson plot may be inaccurate. Scaling by Patterson is also of value for the cross-RF, where different cells are used for the search model and for the unknown structure.

To define the weighting scheme for the X-ray data, *MOLREP* estimates a number of parameters for the search model. Two of them, the radius of gyration of the model (R_g) and the sequence similarity to the target protein (Ω), are translated into the parameters of a low-pass filter and a high-pass filter (Gonzalez & Woods, 2002), which define the resolution dependence of the reflection weights in the RF and TF. It is assumed that the intensities of the low-resolution reflections mostly depend on large-scale details of the crystal and are not very sensitive to the internal features of the molecules. In contrast, the high-resolution reflections define the structural details that are smaller than the differences between the search and the target molecule. The exact measure of this difference is unknown until the structure is solved, but it correlates with the known sequence similarity (Chothia, 1992). The low-pass filter helps to reduce noise in the RF and TF by dampening high-resolution reflections and thus blurring the Patterson map. The low-pass filter is applied to structure factors as an additional B factor,

$$F_{\rm new} = F \exp[-B_{\rm add}(\sin\theta/\lambda)^2]. \qquad (13.5.4.1)$$

The value of $B_{\rm add}$ is based on the sequence similarity and normalized to the Patterson origin peak according to an empirical formula,

$$B_{\rm add} = (B_{\rm lim} - B_{\rm res})(1-\Omega)^4 + B_{\rm res} - B_{\rm over}, \qquad (13.5.4.2)$$

where $B_{\rm lim}$ is the maximum allowed addition to the B factor when no similarity exists ($\Omega = 0$). $B_{\rm lim} = 8\pi^2 u^2$, where u is the mean atomic displacement (1.1 Å). $B_{\rm res}$ is determined from the maximum resolution $R_{\rm max}$ as

$$B_{\rm res} = 2R^2_{\rm max}. \qquad (13.5.4.3)$$

The high-pass filter dampens low-resolution reflections and thus sharpens the Patterson map. The high-pass filter is applied to structure factors as

$$F_{\rm new} = F\{1 - \exp[-B_{\rm off}(\sin\theta/\lambda)^2]\}, \qquad (13.5.4.4)$$

where $B_{\rm off} = 2\pi^2(R_g/6)^2$.

The filter parameters derived automatically from the search model proved to work well in some difficult MR test cases. However, the user may want to define them explicitly when, for example, high sequence similarity between the search and the target protein is in discord with the significant differences in their structures.

13.5.5. Rotational search

The rotational search is performed using the RF of Crowther (1972), which utilizes the fast Fourier transform (FFT) technique. The number of spherical harmonics used in the calculations is limited to 100. Spherical harmonics with $l = 0$ are not included in order to eliminate the effect of the origin Patterson peak. The default radius of the integration sphere is derived from the size of the search model and is usually two times larger than the radius of gyration. However, the Patterson radius should not significantly exceed half of the minimal unit-cell dimension because the contribution of intermolecular vectors becomes significant.

The RF solutions may be refined prior to positional search using a rigid-body technique. The refinement is performed in space group $P1$ and the outcome is evaluated by the correlation coefficient.

13.5.6. Positional search

The full-symmetry TF (Vagin, 1989) originates from the T2 function of Crowther & Blow (1967) corrected by Harada *et al.* (1981). It simultaneously uses all symmetry operators, resulting in a single peak with an improved signal-to-noise ratio which directly gives the position of the model in the unit cell. In addition, the TF is coupled with a PF to remove false maxima which correspond to interpenetrating molecules. Both the TF and PF allow the incorporation of a second model already placed in the cell. The TF solution may be subjected to rigid-body refinement incorporated in *MOLREP*. Noncrystallographic symmetry may be imposed on the model in order to restrain the refinement.

Pseudo-translation is automatically detected from analysis of the Patterson map. A significant off-origin peak gives the pseudo-translation vector, which is used to modify structure factors in the TF calculation (Navaza *et al.*, 1998). Alternatively, the pseudo-translation vector may be supplied by the user. A pseudo-translational copy of the model is added at the end of the positional search.

13.5.7. Multi-copy search

The MR method has been extended to a simultaneous search for multiple copies of the macromolecule in the unit cell (Vagin & Teplyakov, 2000). The central point of this approach is the construction of a dimer search model from the properly oriented monomers using a special TF. This model is then used for a positional search with a conventional TF. The method does not impose any limitation on the oligomeric structure of the protein, either on the number of monomers or on their relative location, *i.e.* pure rotational symmetry is not required. In principle, the monomers may even be of different types. In the case of two monomers, which we call a dyad, the multi-copy search takes place as follows.

(i) The RF is calculated for a monomeric search model. N_R highest peaks of the RF are used to produce a set of oriented monomers. All possible $N_R(N_R + 1)/2$ pair combinations of these monomers constitute a set of putative dyads.

(ii) For each putative dyad, the intermolecular vector relating the two monomers of the dyad is determined using a special TF. The special TF is a phased TF, which treats the Patterson function as electron density, and the search model is described by the structure factors $F_1F_2^*$. The solution of the special TF is the dyad vector. N_T top solutions will be considered to ensure that the correct dyad is not missed. Therefore, the total number of dyads selected for the final positional search will be $N_TN_R(N_R + 1)/2$.

(iii) A positional search for each dyad is performed using a conventional TF. The results are estimated on the basis of the TF value and a correlation coefficient.

The dyad search can be extended to a triad search by including a third monomer in the search model. The phased TF will then be used to find three vectors describing the triad. However, the dyad search seems to be sufficient in most cases, as the main problem is usually the location of the first pair of monomers. When this task is fulfilled, the search can be repeated for a third monomer or a second dyad with the first being fixed.

Although there are no limitations on the relative position and orientation of the two monomers constituting a dyad, the search space can be limited by imposing restraints on the oligomeric structure, *e.g.* by defining the pure rotational symmetry. This feature may be particularly useful in the case of molecular dimers and higher oligomers. Prior knowledge of the molecular symmetry may not only reduce the computational time but may also facilitate the search by selecting functionally meaningful solutions. This can be achieved by defining the angular relation between the monomers, *e.g.* as a $180 \pm 10^\circ$ rotation. Alternatively, the search may be reduced to the use of several top peaks of the self-RF that define a set of possible relative orientations of the monomers in a dyad.

13.5.8. Fitting the model into electron density

This 'real-space' search is employed when some phase information is available either from experimental data (multiple isomorphous replacement or multiwavelength anomalous diffraction) or from a partial MR solution, *e.g.* when one domain of a multi-domain protein has been located in the unit cell. Positioning a model into electron density (or into an EM reconstruction) is carried out in three steps.

(i) The model is positioned in the cell using the spherically averaged TF (Vagin & Isupov, 2001). The locally spherically averaged experimental electron density is compared with that calculated from the model and all possible positions are tabulated.
(ii) For each selected position, the orientation of the model is determined using the local phased RF.
(iii) The orientation and position of the model is verified and refined using the phased TF.

It should be noted that a full six-dimensional search, although time consuming, may in many cases work better. However, compared with traditional (3 + 3)-dimensional searches the fitting based on the spherically averaged phased TF may be advantageous, particularly when the search model is small. In general, the procedure works better for globular models.

The same procedure is used for the superposition of atomic models. One model is converted to the electron-density map and another model is fitted to this map using the spherically averaged and phased TF and RF. No sequence information or secondary-structure assignment is required for such a superposition. The procedure may be useful for proteins with very low sequence similarity. It is also suitable for nonprotein models such as nucleic acids or carbohydrates.

13.5.9. Distribution

The program *MOLREP* is written in standard Fortran 90 and can be run under Linux, Unix, Mac OSX and Windows. It is available free to academic users as a standalone version or as part of the *CCP*4 suite. The program, examples and documentation may be downloaded from the author's web site (http://www.ysbl.york.ac.uk/~alexei/molrep.html) or from the CCP4 web site. All inquiries about the program should be addressed to Alexei Vagin (alexei@ysbl.york.ac.uk).

We thank Andrey Lebedev for his contribution to the program and helpful discussions. This work was supported by CCP4, the Biotechnology and Biological Sciences Research Council (BBSRC) and EU Biotech.

This chapter is based on a recent article published in *Acta Crystallographica Section D* (Vagin & Teplyakov, 2010).

PART 14. ANOMALOUS DISPERSION

Chapter 14.1. Heavy-atom location and phase determination with single-wavelength diffraction data

B. W. Matthews

14.1.1. Introduction

As is well known, the successful introduction of the method of isomorphous replacement by Green *et al.* (1954) was the turning point in the subsequent development of protein crystallography as we now know it.

The idea that the phases of X-ray reflections from a protein crystal could be obtained by the introduction of heavy atoms into the crystal was not new, having been suggested by J. D. Bernal in 1939 (Bernal, 1939). The isomorphous-replacement method was used as early as 1927 by Cork (1927) in studying the alums. Bokhoven *et al.* (1951) subsequently extended the method to the study of a noncentrosymmetric projection of strychnine sulfate, using what would now be termed the method of single isomorphous replacement. They also suggested that by using a double isomorphous replacement, a unique phase determination could be obtained, even for noncentrosymmetric reflections. The details of the double (or multiple) isomorphous-replacement method were worked out by Harker (1956), who introduced the very useful concept of phase circles. Another contribution which was of great practical value, and which will provide the basis for much of the subsequent discussion, is the method introduced by Blow & Crick (1959) for the treatment of errors in the isomorphous-replacement method. In addition to the determination of protein phases by the method of substitution with heavy atoms, it is now routine to supplement this information by utilizing the anomalous scattering of the substituted atoms. The underlying principles trace back to articles by Bijvoet (1954), Ramachandran & Raman (1956), and Okaya & Pepinsky (1960). The first application of the anomalous-scattering method to protein crystallography was by Blow (1958), who used the anomalous scattering of the iron atoms to determine phase information for a noncentrosymmetric projection of horse oxyhaemoglobin.

In the following discussion, we first review the classical method of phase determination by isomorphous replacement, then discuss the inclusion of single-wavelength anomalous-scattering data, and conclude by discussing the use of such data for heavy-atom location. Part of the review is based on Matthews (1970).

14.1.2. The isomorphous-replacement method

Consider a protein crystal with an isomorphous heavy-atom derivative, *i.e.* a modified crystal in which heavy atoms occupy specific sites throughout the crystal, but which is in all other respects identical to the unsubstituted 'parent' crystal. Let the structure factors of the protein crystal be $\mathbf{F}_P(\mathbf{h})$, of the isomorph be $\mathbf{F}_{PH}(\mathbf{h})$, and of the heavy atoms $\mathbf{F}_H(\mathbf{h})$. (Note: Structure *amplitudes* are indicated by italic type, *e.g.* F_P, and *vectors* by bold-face type, *e.g.* $\mathbf{F}_P$.) In practice, one can measure the structure amplitudes F_P and F_{PH}, and it is desired to obtain from these observable quantities the value of the phase angle of $\mathbf{F}_P(\mathbf{h})$ so that a Fourier synthesis showing the electron density of the protein structure may be calculated. It will be assumed, for the moment, that the positions and occupancy of the sites of heavy-atom binding have been determined as accurately as possible.

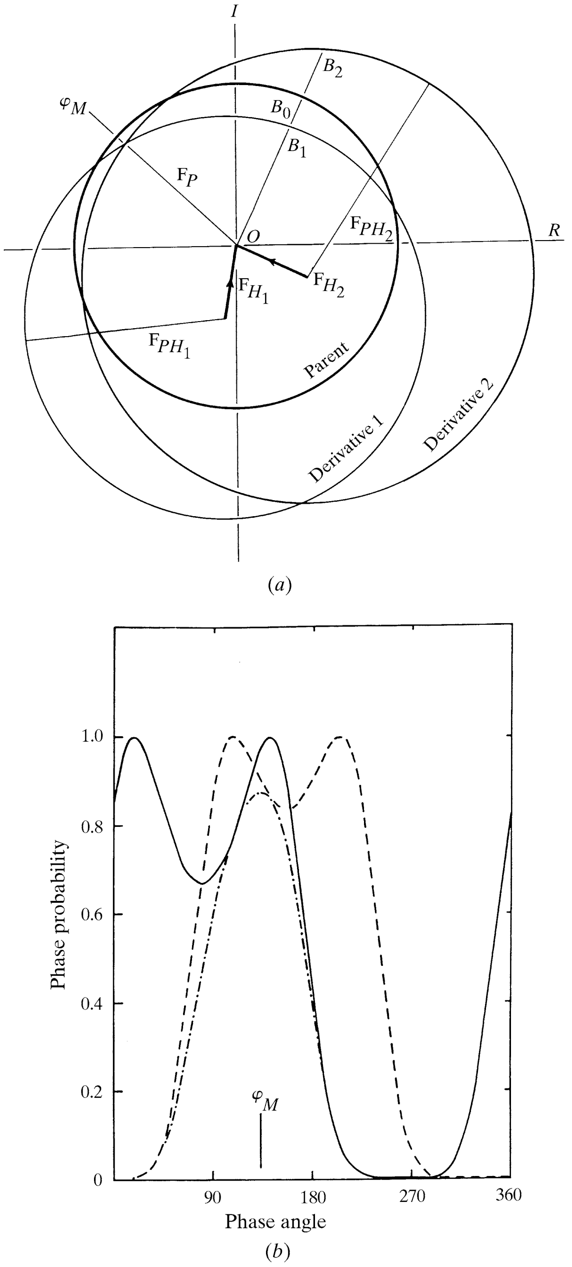

Figure 14.1.3.1
(*a*) Harker construction for a double isomorphous replacement. φ_M is the 'most probable' phase for $\mathbf{F}_P$. (*b*) Phase probability distribution corresponding to the double isomorphous replacement shown in part (*a*). The curve for derivative 1 is solid, that for derivative 2 is dashed, and that for the combined distribution is drawn as a dotted-and-dashed line.

From the heavy-atom parameters, the corresponding structure factor $\mathbf{F}_H(\mathbf{h})$ is calculated. To determine φ, the phase of $\mathbf{F}_P(\mathbf{h})$, we construct a set of phase circles, as proposed by Harker (1956). From a chosen origin O (Fig. 14.1.2.1*a*), the vector OA is drawn equal to $-\mathbf{F}_H$. Circles of radius F_P and F_{PH} are then drawn about O and A, respectively. The intersections of the phase circles at B and B' define two possible phase angles for F_P. Note that the angles are symmetrical about $\mathbf{F}_H$. This ambiguity may in principle be resolved in two ways: (*a*) by using a second heavy-atom isomorphous derivative or (*b*) by utilizing the anomalous-scattering effects for the first isomorph.

14.1.3. The method of multiple isomorphous replacement

The phase information provided by a second isomorph is illustrated in Fig. 14.1.3.1(*a*). In theory, the three phase circles will intersect at a point and the phase ambiguity will be resolved. In practice, there will be errors in the observed amplitudes F_P and F_{PH} and in the heavy-atom parameters (and thus in $\mathbf{F}_H$). Also, the isomorphism may be imperfect. As a result, the intersections of the three phase circles may not coincide. Another complication arises from the fact that for reflections where $\mathbf{F}_H$ is small, the circles will be essentially concentric and will not have well defined points of intersection. In other words, the phase determination will become indeterminate. The method of Blow & Crick (1959) was introduced as a way to take all these factors into account. It has had an extraordinary impact, not only as a practical method for protein phase determination, but also in influencing all subsequent thinking in this area.

14.1.4. The method of Blow & Crick

Blow & Crick pointed out that in practice the phase angle φ can never be determined with complete certainty. Rather, there is a finite probability that any arbitrary phase angle may be the correct one. Consider the vector diagram shown in Fig. 14.1.4.1, in which $\mathbf{F}_H$ is known and we wish to determine the probability $P(\varphi)$ that the arbitrary phase angle φ is the correct phase of $\mathbf{F}_P$. Strictly, one should allow for the possibility of errors in $\mathbf{F}_H$, F_P and F_{PH}, and should consider the probability that the vector $\mathbf{F}_P$ occupies all possible positions in the Argand diagram. However, Blow & Crick suggested that the analysis might be considerably simplified by assuming that F_P and $\mathbf{F}_H$ are known accurately and that all the error lies in the observation of F_{PH}. In other words, it was assumed that the vector $\mathbf{F}_P$ must lie on the circle of radius F_P, and the probability distribution of F_P could be evaluated as a function of φ only.

For an arbitrary phase angle φ, the phase triangle (Fig. 14.1.4.1) will not close exactly. If we define F_C to be the vector sum of $\mathbf{F}_H$ and $F_P \exp(i\varphi)$, then the lack of closure of the phase triangle is given by

$$\varepsilon = F_C - F_{PH}. \qquad (14.1.4.1)$$

Following Blow & Crick, if E is the r.m.s. error associated with the measurements, and the distribution of error is assumed to be Gaussian, then the probability $P(\varphi)$ of the phase φ being the true phase is

$$P(\varphi) = N \exp(-\varepsilon^2/2E^2), \qquad (14.1.4.2)$$

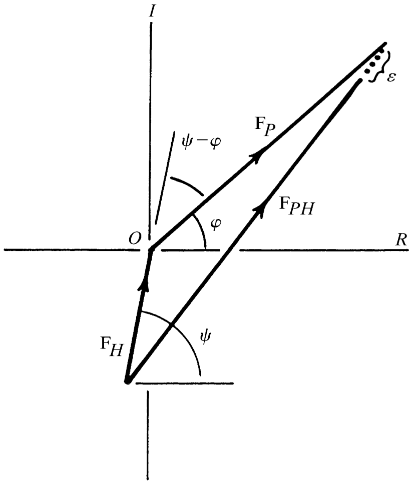

Figure 14.1.4.1
Vector diagram illustrating the lack of closure, ε, of an isomorphous-replacement phase triangle.

where N is a normalizing factor such that the sum of all probabilities is unity. The un-normalized probability distribution corresponding to Fig. 14.1.4.1 (and Fig. 14.1.2.1*a*) is shown in Fig. 14.1.2.1(*b*). The two most probable phase angles ($\varphi = \varphi_1$ and $\varphi = \varphi_2$) are the alternative phases of F_P for which the phase triangle is closed.

Individual probability distributions for the additional heavy-atom derivatives are derived in an analogous manner and may be multiplied together to give an overall probability distribution. The joint probability distribution corresponding to Fig. 14.1.3.1(*a*) is shown in Fig. 14.1.3.1(*b*), and in this case the most probable phase is that which simultaneously fits best the observed data for the two isomorphous derivatives.

The main objection which may be made to the Blow & Crick treatment is that it assumes that there is no error in F_P. In practice, however, this is not a serious limitation.

14.1.5. The best Fourier

A protein crystallographer desires to obtain a Fourier synthesis that can most readily be interpreted in terms of an atomic model of the structure. One synthesis which could be calculated is the 'most probable Fourier', obtained by choosing the value of $F_P(\mathbf{h})$ for each reflection which corresponds to the highest value of $P(\varphi)$. Blow & Crick pointed out that although this Fourier is the most likely to be correct, it has certain disadvantages. In the first place, it might tend to give too much weight to uncertain or unreliable phases, and, in the second place, for cases where $P(\varphi)$ is bimodal, there is a strong chance of making a large error in the phase angle. Blow & Crick suggested that in cases such as this, a compromise is needed, and that the centroid of the phase probability distribution provides just the required compromise. They showed that the corresponding synthesis is the 'best Fourier', which is defined to be *that Fourier transform which is expected to have the minimum mean-square difference from the Fourier transform of the true F's when averaged over the whole unit cell.*

The centroid of the phase probability distribution may be defined as a point on the phase diagram with polar coordinates (mF_P, φ_B), where φ_B is the 'best' phase angle. The quantity m, which acts as a weighting factor for F_P, is called the 'figure of merit' of the phase determination. Its magnitude, between 0 and 1, is a measure of the reliability of the phase determination.

14.1.6. Anomalous scattering

All atoms, particularly those used in preparing heavy-atom isomorphs, give rise to anomalous scattering, especially if the energy of the scattered X-rays is close to an absorption edge. The atomic scattering factor of the atom in question can be expressed as

$$\mathbf{f} = f_0 + \Delta f' + if'' = f' + if'', \qquad (14.1.6.1)$$

where f_0 is the normal scattering factor far from an absorption edge, and $\Delta f'$ and f'' are the correction terms which arise due to dispersion effects. The quantity $\Delta f'$, in phase with f_0, is usually negative, and f'', the imaginary part, is always $\pi/2$ ahead of the phase of the real part ($f_0 + \Delta f'$). It may be noted that by using different wavelengths, the term $\Delta f'$ is equivalent to a change in scattering power of the heavy atom and produces intensity differences similar to a normal isomorphous replacement, except that in this case the isomorphism is *exact* (Ramaseshan, 1964). This is the basis of the multiwavelength-anomalous-dispersion (MAD) method (Hendrickson, 1991) discussed in Chapter 14.2. Here we focus on measurements based on a single wavelength, traditionally referred to as the 'anomalous-scattering method'.

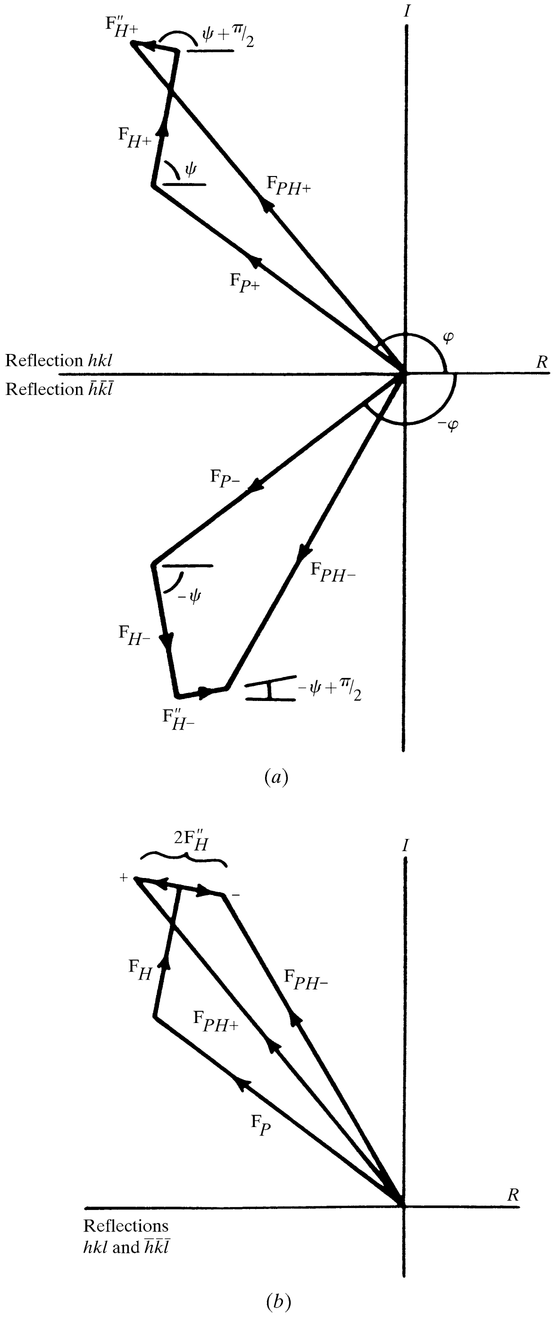

Figure 14.1.7.1
(*a*) Vector diagrams illustrating anomalous scattering for the reflections *hkl* and $\overline{hkl}$. (*b*) Combined vector diagram for reflections *hkl* and $\overline{hkl}$.

The anomalous scattering of a heavy atom is always considerably less than the normal scattering (for Cu $K\alpha$ radiation, $2f''/f'$ ranges from about 0.24 to 0.36), but there are several factors which tend to offset this reduction in magnitude (*e.g.* see Blow, 1958; North, 1965).

14.1.7. Theory of anomalous scattering

Suppose that two isomorphous crystals are differentiated by N heavy atoms of position $\mathbf{r}_n$ and scattering factor $(\mathbf{f}'_n + i\mathbf{f}''_n)$. Then, for the reflection *hkl*, the calculated structure factor of the N atoms is

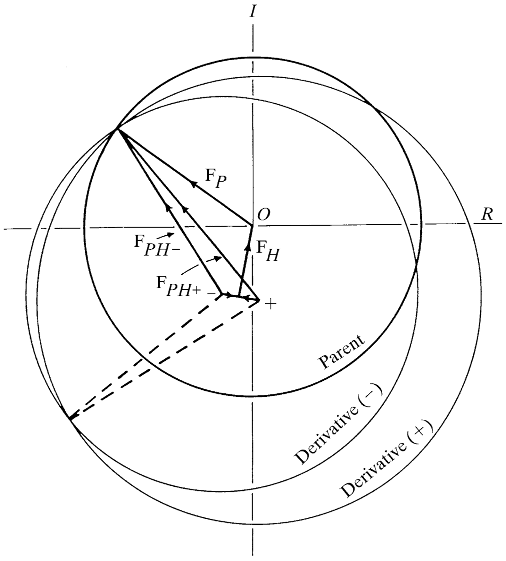

Figure 14.1.7.2
Harker construction for a single isomorphous replacement with anomalous scattering, in the absence of errors.

$$F_H(\mathbf{h}) + iF''_H(\mathbf{h}) = \sum_{n=1}^{N} f'_n(\mathbf{h}) \exp(2\pi i \mathbf{h} \cdot \mathbf{r}_n) + i \sum_{n=1}^{N} f''_n(\mathbf{h}) \exp(2\pi i \mathbf{h} \cdot \mathbf{r}_n). \qquad (14.1.7.1)$$

If the heavy atoms are all of the same type, *i.e.* they all have the same ratio of f'_n/f''_n $(= k)$, then F_H and F''_H are orthogonal, and $F''_H = F_H/k$.

The relation between the structure factors of the reflection *hkl* and its Friedel mate $\bar{h}\bar{k}\bar{l}$ is illustrated in Fig. 14.1.7.1(*a*). The situation can be conveniently represented (Fig. 14.1.7.1*b*) by reflecting the $\bar{h}\bar{k}\bar{l}$ diagram through the real axis onto the *hkl* diagram. In cases such as this, where Friedel's law breaks down, we shall refer to the difference $\Delta_{PH} = (F_{PH+} - F_{PH-})$ as the Bijvoet difference, or simply the anomalous-scattering difference. The Harker phase circles corresponding to Fig. 14.1.7.1(*b*) are shown in Fig. 14.1.7.2. It will be seen that, as in the case of single isomorphous replacement, and similarly with the anomalous-scattering data alone, there is an ambiguous phase determination.

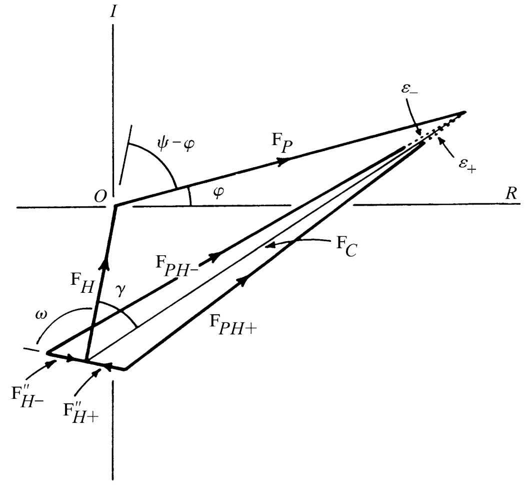

Figure 14.1.8.1
Vector diagrams illustrating lack of closure in the anomalous-scattering method.

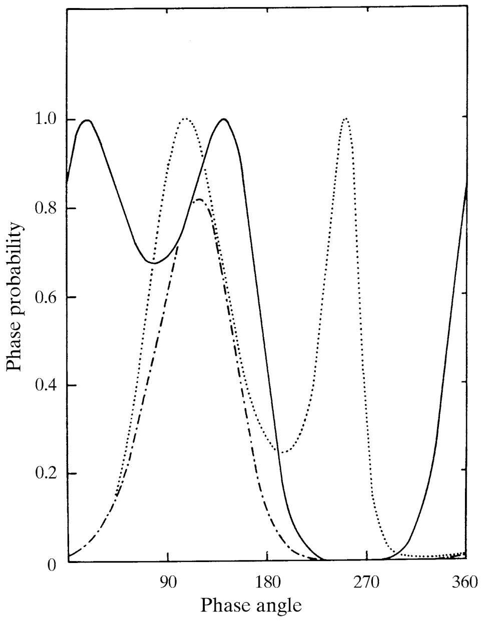

Figure 14.1.8.2
Combination of isomorphous replacement and anomalous-scattering phase probabilities for a single isomorphous replacement. $P_{\rm iso}(\varphi)$ is drawn as a solid line, $P_{\rm ano}(\varphi)$ as a dotted line, and the combined probability distribution is drawn as a dotted-and-dashed line.

In the absence of error, the three phase circles (Fig. 14.1.7.2) will meet at a point, resolving the phase ambiguity and giving a unique solution for the phase of $\mathbf{F}_P$. The isomorphous-replacement method gives phase information symmetrical about the vector $\mathbf{F}_H$, whereas the anomalous-scattering phase information for $\mathbf{F}_{PH}$ is symmetrical about $\mathbf{F}''_H$, which, for heavy atoms of the same type, is at right angles to $\mathbf{F}_H$. In other words, the two methods complement each other, one method providing exactly that information which is not given by the other.

On average, the experimentally measured isomorphous-replacement difference, $(F_{PH} - F_P)$, will be larger than the anomalous-scattering difference, $(F_{PH+} - F_{PH-})$. The former, however, relies on measurements from different crystals and is also susceptible to errors due to non-isomorphism between the parent and derivative crystals. The latter can be obtained from measurements on the same crystal, under closely similar experimental conditions, and is not affected by non-isomorphism. Therefore, it is desirable to use methods that take into account the different sources of error in the respective measurements (Blow & Rossmann, 1961; North, 1965; Matthews, 1966*b*). One method is as follows.

14.1.8. The phase probability distribution for anomalous scattering

From Fig. 14.1.8.1, it can be seen that the most probable phase angle will be the one for which $\varepsilon_+ = \varepsilon_-$. At any other phase angle, there will be an 'anomalous-scattering lack of closure' which we define to be $(\varepsilon_+ - \varepsilon_-)$. The value of $(\varepsilon_+ - \varepsilon_-)$ can readily be calculated as a function of φ (Matthews, 1966*b*; Hendrickson, 1979). Thus, if the r.m.s. error in $(\varepsilon_+ - \varepsilon_-)$ is E', and the distribution of error is assumed to be Gaussian, then from measurements of anomalous scattering, the probability $P_{\rm ano}(\varphi)$ of phase φ being the true phase of $\mathbf{F}_P$ can be estimated using an equation exactly analogous to equation (14.1.4.2).

An example of an anomalous-scattering phase probability distribution is shown by the dotted curve in Fig. 14.1.8.2. The asymmetry of the distribution arises from the fact that $P_{\rm ano}(\varphi)$ is the phase probability distribution for F_P rather than that of F_{PH}, which would be symmetrical about the phase of F''_H. The overall probability distribution obtained by combining the anomalous-scattering data with the previous isomorphous-replacement data (Fig. 14.1.2.1*b*) is given by

$$P(\varphi) = NP_{\rm iso}(\varphi)P_{\rm ano}(\varphi) \qquad (14.1.8.1)$$

and is illustrated in Fig. 14.1.8.2.

14.1.9. Anomalous scattering without isomorphous replacement

The treatment outlined above of phase determination by anomalous scattering assumed that data were available for a parent crystal devoid of anomalous scatters and an anomalously scattering isomorphous heavy-atom derivative. It is not uncommon that the native protein itself contains atoms which scatter anomalously or has been engineered to contain such scatterers. In such cases, measurements will usually be made at multiple wavelengths in order to exploit MAD phasing (Hendrickson, 1991). If, however, measurements are available only at a single wavelength, they can be utilized to obtain some phase information (*e.g.* Matthews, 1970).

14.1.10. Location of heavy-atom sites

During the development of protein crystallography, it was understood that heavy-atom sites might be located from difference Patterson functions, but there was substantial debate as to the type of function that was preferable (Perutz, 1956).

Blow (1958), and also Rossmann (1960), advocated a Patterson function with amplitudes $(F_{PH} - F_P)^2$. It relies on the admittedly crude assumption that the desired scattering amplitude of the heavy atoms, $|F_H|$, can be approximated by

$$|F_H| \simeq |F_{PH} - F_P|. \qquad (14.1.10.1)$$

The approximation does have one very helpful characteristic, namely, that it tends to be most accurate when $|F_{PH} - F_P|$ is large, *i.e.* when F_H is parallel or antiparallel to F_P (*cf.* Fig. 14.1.4.1). Thus, the numerically largest coefficients in the Patterson function tend to represent $|F_H|^2$ correctly. Given a well behaved isomorphous heavy-atom derivative, and accurately measured data, experience has shown that a map with coefficients $(F_{PH} - F_P)^2$ can give an excellent representation of the desired heavy-atom–heavy-atom vector peaks.

14.1.11. Use of anomalous-scattering data in heavy-atom location

A relation exactly analogous to equation (14.1.10.1) can be used to approximate the anomalous heavy-atom scattering amplitude, namely,

$$|F''_H| \simeq \tfrac{1}{2}|F_{PH+} - F_{PH-}| \qquad (14.1.11.1)$$

(see Fig. 14.1.7.1*b*). As noted above, if all the heavy atoms are the same, $F_H = kF''_H$. Thus, a Patterson function with coefficients $(F_{PH+} - F_{PH-})^2$ should also show the desired heavy-atom–heavy-atom vector peaks (Blow, 1957; Rossmann, 1961).

For each individual reflection, however, and as is also the case for phase determination, the information that is provided by the isomorphous-replacement difference $(|F_{PH}| - |F_P|)$ is exactly complementary to that provided by the anomalous-scattering measurement $(|F_{PH+}| - |F_{PH-}|)$. By combining both sets of experimental measurements, it is possible to obtain a much better estimate of the heavy-atom scattering, $|F_H|$, for every reflection (Kartha & Parthasarathy, 1965*a*,*b*; Matthews, 1966*a*; Singh & Ramaseshan, 1966). One formulation (Matthews, 1966*a*) can be written as

$$F_H^2 = F_P^2 + F_{PH}^2 - 2F_PF_{PH}\{1 - [wk(F_{PH+} - F_{PH-})/2F_P^2\}^{1/2}, \qquad (14.1.11.2)$$

where $F_{PH} = (F_{PH+} + F_{PH-})/2$ and w is a weighting factor (from 0 to 1) that is an estimate of the relative reliability of the measurements of $(F_{PH+} - F_{PH-})$ compared with $(F_{PH} - F_P)$.

14.1.12. Use of difference Fourier syntheses

The discussion above has focused on the use of difference Patterson functions to locate heavy-atom sites. Once one or more putative sites have been located, they can be used to calculate approximate protein phases, which, in turn, can be used to calculate difference Fourier series with coefficients in the form

$$m(F_{PH} - F_H)\exp(-i\varphi_B), \qquad (14.1.12.1)$$

where m is the figure of merit and φ_B is the 'best', albeit approximate, phase of the protein structure factor. Putting aside errors due to inaccuracies in φ_B, such maps do not give the true heavy-atom vector, $\mathbf{F}_H$. Rather, they give, essentially, the projection of $\mathbf{F}_H$ along $\mathbf{F}_P$ (*cf.* Fig. 14.1.4.1). Nevertheless, subject to certain limitations, such difference maps are extraordinarily powerful in locating secondary sites in a given heavy-atom derivative, or in using approximate phases from one derivative to search for heavy-atom sites in other putative derivatives. It is in this context, however, that certain limitations of the single-isomorphous-replacement (SIR) method have to be kept in mind. These are noted in the next section.

14.1.13. Single isomorphous replacement

Although phase determination from a single heavy-atom derivative in the absence of anomalous-scattering data is, in principle, ambiguous, it was realized early on that useful phase information can still be obtained (Blow & Rossmann, 1961). As shown in Fig. 14.1.2.1(*a*), the two possible phases for the protein are φ_1 or φ_2. In terms of the analysis of Blow & Crick (1959), the 'best' phase to use for the protein is the average of φ_1 and φ_2. This is also equivalent to using *both* φ_1 *and* φ_2. With this in mind, a situation that is of special concern is one in which the heavy-atom distribution used to determine the phases happens to have a centre of symmetry. One common way in which this can occur is when one has a heavy-atom derivative with a single site in space group $P2_1$. A related situation occurs when there are multiple sites in space group $P2_1$, but all have the same y coordinate. If the origin of coordinates is considered to be at the site of centrosymmetry, then all of the heavy-atom vectors $\mathbf{F}_H$ (Fig. 14.1.2.1*a*) will necessarily have phases of 0 or π. If such phases are used, for example, to try to identify heavy-atom-binding sites in a second derivative, the map will show the correct sites, but will also show spurious peaks of equal height related by the centre of symmetry. Faced with this choice, one must arbitrarily choose one of the alternative peaks which, in turn, will define an overall handedness for the heavy-atom arrangement. In the absence of any anomalous-scattering data, one can proceed with the structure determination in the standard way, but it must be kept in mind that either the correct electron-density map or its mirror image will ultimately be obtained.

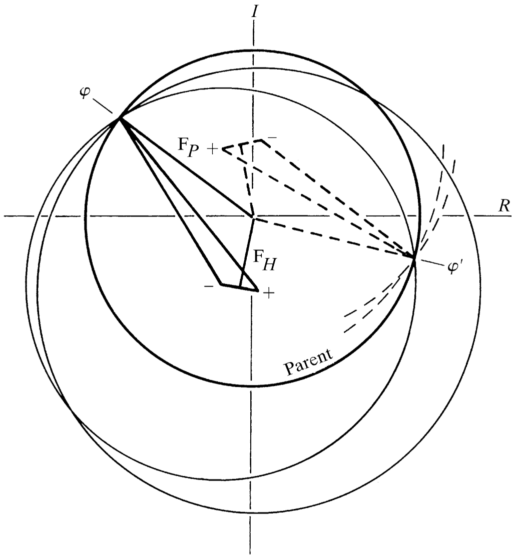

Figure 14.1.13.1

The consequences of using the incorrect hand for the heavy-atom arrangement in phase determination. The correct heavy-atom arrangement gives the construction drawn in solid lines with φ uniquely determined as the correct phase for $\mathbf{F}_P$. If the enantiomeric arrangement of heavy atoms is used, the dashed construction will result, leading to the incorrect phase φ'. Even though φ is correct and φ' is incorrect, both phase determinations have an identical figure of merit.

An alternative approach is to include anomalous-scattering data in the initial phase determination, *i.e.* to use single isomorphous replacement with anomalous scattering (SIRAS). It must be remembered that in calculating phases from anomalous-scattering data, it is first necessary to determine the coordinates of the heavy atoms *in their absolute configuration.* If the wrong hand is used in the SIRAS method (illustrated in Fig. 14.1.13.1), the resultant electron-density map will generally bear no relation to the correct electron density.

The recommended procedure, therefore, is as follows. One arbitrarily chooses one possible heavy-atom arrangement for heavy-atom derivative 1, calculates SIRAS phases and calculates a difference-electron-density map for derivative 2. The handedness of the derivative 1 coordinates are then inverted and the overall calculation repeated. The calculation based on the correct heavy-atom arrangement should show peaks at the heavy-atom sites of the second derivative. The calculation based on the incorrect arrangement shows noise (Matthews, 1966*a*). This procedure determines the absolute configuration of the heavy-atom arrangement and, at the same time, shows the derived sites for the second and subsequent derivatives.

Chapter 14.2. Multiwavelength anomalous diffraction

J. L. Smith and W. A. Hendrickson

Anomalous-scattering effects measured at several X-ray wavelengths can provide a direct solution to the crystallographic phase problem. For many years this was appreciated as a hypothetical possibility (Okaya & Pepinsky, 1956), but, until tunable synchrotron radiation became available, experimental investigation with the weakly diffracting crystals of biological macromolecules was limited to one heroic experiment (Hoppe & Jakubowski, 1975). Multiwavelength anomalous diffraction (MAD) became a dominant phasing method in macromolecular crystallography with the advent of reliable, brilliant synchrotron-radiation sources, the adoption of cryopreservation techniques for crystals of macromolecules, and the development of general anomalous-scatterer labels for proteins and nucleic acids.

Anomalous scattering, first recognized as a source of phase information by Bijvoet (1949), has been employed since the early days of macromolecular crystallography (Blow, 1958). It has been used to locate positions of anomalous scatterers (Rossmann, 1961), to supplement phase information from isomorphous replacement (North, 1965; Matthews, 1966*a*) and to identify the enantiomorph of the heavy-atom partial structure in multiple isomorphous replacement (MIR) phasing (Matthews, 1966*b*). Anomalous scattering at a single wavelength was the sole source of phase information in the structure determination of crambin (Hendrickson & Teeter, 1981), an important precursor to development of MAD. MAD differs from these other applications in using anomalous scattering at several wavelengths for complete phase determination without approximations or simplifying assumptions.

14.2.1. Anomalous scattering factors

The scattering of X-rays by an isolated atom is described by the atomic scattering factor, f^0, based on the assumption that the electrons in the atom oscillate as free electrons in response to X-ray stimulation. The magnitude of f^0 is normalized to the scattering by a single electron. Thus the 'normal' scattering factor f^0 is a real number, equal to the Fourier transform of the electron-density distribution of the atom. At zero scattering angle ($s = \sin\theta/\lambda = 0$), f^0 equals Z, the atomic number. f^0 falls off rapidly with increasing scattering angle due to weak scattering by the diffuse parts of the electron-density distribution. In reality, electrons in an atom do not oscillate freely because they are bound in atomic orbitals. Deviation from the free-electron model of atomic scattering is known as anomalous scattering. Using a classical mechanical model (James, 1948), an atom scatters as a set of damped oscillators with resonant frequencies matched to the absorption frequencies of the electronic shells. The total atomic scattering factor, f, is thus a complex number. f is denoted as a sum of 'normal' and 'anomalous' components, where the anomalous components are corrections to the free-electron model:

$$f = f^0 + f' + if''. \qquad (14.2.1.1)$$

f' and f'' are expressed in electron units, as is f^0. The real component of anomalous scattering, f', is in phase with the normal scattering, f^0, whilst the imaginary component, f'', is out of phase by $\pi/2$.

The imaginary component of anomalous scattering, f'', is proportional to the atomic absorption coefficient of the atom, μ_a, at X-ray energy E:

$$f''(E) = (mc/4\pi e^2\hbar)E\mu_a(E), \qquad (14.2.1.2)$$

where m is the electronic mass, c is the speed of light, e is the electronic charge and h $(= 2\pi\hbar)$ is Planck's constant. Thus, f'' can be determined experimentally by measurement of the atomic absorption coefficient. The relationship between f'' and f' is known as the Kramers–Kronig dispersion relation (James, 1948; Als-Nielsen & McMorrow, 2001):

$$f'(E) = \left(\frac{2}{\pi}\right) P \int\limits_0^\infty \frac{E'f''(E')}{E^2 - E'^2}\,\mathrm{d}E', \qquad (14.2.1.3)$$

where P represents the Cauchy principal value of the integral such that integration over E' is performed from 0 to $(E - \varepsilon)$ and from $(E + \varepsilon)$ to ∞, and then the limit $\varepsilon \to 0$ is taken. The principal value of the integral can be evaluated numerically from limited spectral data that have been scaled to theoretical f'' scattering factors (or μ_a absorption coefficients) at points remote from the absorption edge.

Anomalous scattering is present for all atomic types at all X-ray energies. However, the magnitudes of f' and f'' are negligible at X-ray energies far removed from the resonant frequencies of the atom. This includes all light atoms (H, C, N, O) of biological macromolecules at all X-ray energies commonly used for crystallography. f' and f'' are rather insensitive to scattering angle, unlike f^0, because the electronic resonant frequencies pertain to inner electron shells, which have radii much smaller than the X-ray wavelengths used for anomalous-scattering experiments. The magnitudes of f' and f'' are greatest at X-ray energies very near resonant frequencies, and are also highly energy-dependent (Fig. 14.2.1.1). This property of anomalous scattering is exploited in MAD.

Three means are available for evaluating anomalous scattering factors, f' and f''. Calculations from first principles on isolated elemental atoms are accurate for energies remote from resonant frequencies (Cromer & Liberman, 1970*a*,*b*). However, these calculated values do not apply to the energies most critical in a MAD experiment. f' and f'' can also be estimated by fitting to diffraction data measured at different energies (Templeton *et al.*, 1982). Finally, f'' can be obtained from X-ray absorption spectra by the equation above, and f' from f'' by the Kramers–Kronig transform [equation (14.2.1.3); Hendrickson *et al.*, 1988; Smith, 1998]. Both the precise position of a resonant frequency and the values of f' and f'' near resonance generally depend on transitions to unoccupied molecular orbitals, and are quite sensitive to the electronic environment surrounding the atom. Complexities in the X-ray absorption edge, particularly so-called 'white lines', can enhance the anomalous scattering considerably (Fig. 14.2.1.1). Thus, experimental measurements are needed to select wavelengths for optimal signals, and the values of f' and f'' should be determined either from an absorption spectrum or by refinement against the diffraction data.

X-ray spectra near absorption edges of anomalous scatterers depend on the orientation of the local chemical environment in the X-ray beam, which is polarized for synchrotron radiation. The anisotropy of anomalous scattering may affect both the edge position and the magnitude of absorption. In such cases, f' and f'' for individual atoms are also dependent on orientation. Orientational averaging due to multiple anomalous scatterer sites or crystallographic symmetry may prevent macroscopic detection of polarization effects in crystals. A formalism to describe anisotropic anomalous scattering in which f' and f'' are tensors has been developed by Templeton & Templeton (1988). Fanchon & Hendrickson (1990) have developed a technique to refine f' and f'' tensors against MAD data. Although anomalous scattering labels such as the commonly used selenomethionine and related compounds are strongly anisotropic (Templeton & Templeton, 1988; Hendrickson *et al.*, 1990), anisotropy is generally ignored in MAD for biological macromolecules.

14.2.2. A phase equation for MAD

The impact of anomalous scattering on diffraction measurements can be evaluated by substituting the scattering-factor expression [equation (14.2.1.1)] into the structure-factor equation.

$$ {}^{\lambda}F_{\rm obs}(\mathbf{h}) = \sum_{i=1}^{\text{No. of atoms}} (f^0 + f'_{\lambda} + if''_{\lambda})_i \exp[-B_i s^2(\mathbf{h})] \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_i). \qquad (14.2.2.1) $$

It is convenient to separate terms in the structure-factor expression according to wavelength dependence (Karle, 1980). A wavelength-independent structure factor ${}^{0}F_T$ with phase φ_T is defined to represent the total normal scattering from all atoms (Hendrickson, 1985) as

$$ \begin{aligned} {}^{0}F_T(\mathbf{h}) &= \sum_{i=1}^{\text{No. of atoms}} f_i^0 \exp\left[-B_i s^2(\mathbf{h})\right] \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_i) \\ &= |{}^{0}F_T| \exp(i\varphi_T). \end{aligned} \qquad (14.2.2.2) $$

The anomalous scattering is confined to wavelength-dependent 'anomalous' structure factors ${}^{\lambda}\mathbf{F}'$ and ${}^{\lambda}\mathbf{F}''$, representing the real and imaginary components of anomalous scattering for all atoms. In general, the anomalous structure factors are considered for only the subset of atoms with detectable anomalous scattering, leading to the anomalous structure factors ${}^{\lambda}\mathbf{F}'_A$ and ${}^{\lambda}\mathbf{F}''_A$:

$$ {}^{\lambda}F'_A(\mathbf{h}) = \sum_{j=1}^{N_{\rm ano}} f'_{\lambda j} \exp\left[-B_j s^2(\mathbf{h})\right] \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_j) \qquad (14.2.2.3) $$

$$ {}^{\lambda}F''_A(\mathbf{h}) = \sum_{j=1}^{N_{\rm ano}} if''_{\lambda j} \exp\left[-B_j s^2(\mathbf{h})\right] \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_j), \qquad (14.2.2.4) $$

where $N_{\rm ano}$ is the number of anomalous scatterers. The anomalous structure factors ${}^{\lambda}F'_A$ and ${}^{\lambda}F''_A$ can also be expressed in terms of the normal structure-factor components, ${}^{0}F_{A_k}$ with phase φ_{A_k}, for the subsets of atoms that comprise each kind of anomalous scatterer (Karle, 1980),

$$ {}^{\lambda}F'_A = \sum_{k=1}^{\text{No. of kinds}} (f'_{\lambda}/f^0)_k \, {}^{0}F_{A_k} \qquad (14.2.2.5) $$

$$ {}^{\lambda}F''_A = \sum_{k=1}^{\text{No. of kinds}} (if''_{\lambda}/f^0)_k \, {}^{0}F_{A_k}. \qquad (14.2.2.6) $$

Thus, the wavelength-dependent experimental structure factor ${}^{\lambda}F_{\rm obs}$ can be represented using normal structure factors only:

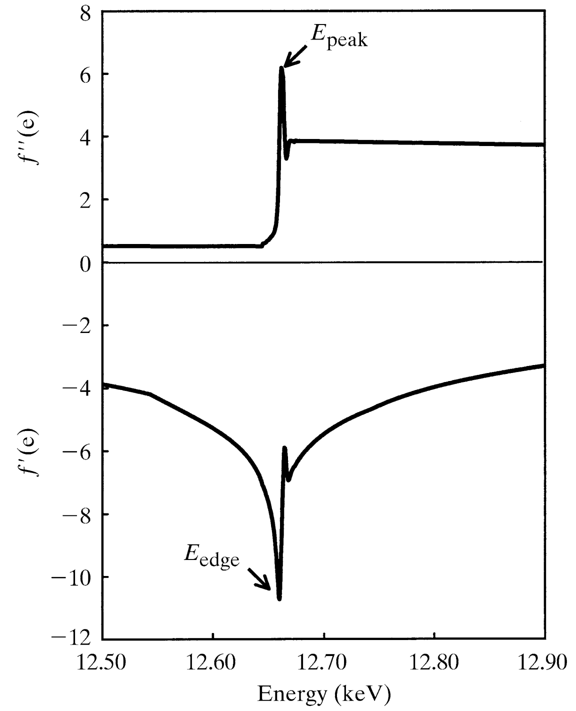

Figure 14.2.1.1
Anomalous scattering factors for Se in a protein labelled with selenomethionine. The spectra are a hybrid of experimental values derived from an absorption spectrum of a SeMet protein for energies near the Se K absorption edge and calculated values for energies remote from the edge. The Se K edge occurs at 12 660 eV, corresponding to a wavelength of 0.9800 Å. Anomalous-scattering effects are enhanced by a white line just above the edge. The position of the absorption edge ($E_{\rm edge}$) is the inflection point of the μ_a (and f'') spectrum, and $E_{\rm peak}$ is the energy of peak absorption just above the edge. These energies correspond to the wavelengths $\lambda_{\rm edge}$ and $\lambda_{\rm peak}$ in a MAD experiment because the magnitudes of f' and f'' are greatest at $E_{\rm edge}$ and $E_{\rm peak}$, respectively.

$$ {}^{\lambda}F_{\rm obs} = {}^{0}F_T + \sum_{k=1}^{\text{No. of kinds}} \left(\frac{f'_{\lambda}}{f^0} + i\frac{f''_{\lambda}}{f^0} \right)_k {}^{0}F_{A_k} \qquad (14.2.2.7) $$

This factorization is convenient because all wavelength dependence is confined to the anomalous scattering factors f' and f'', which are independent of atomic positions, occupancies and thermal parameters. In addition, an electron-density map for the total structure should be based on normal scattering by all atoms, represented by the structure factor ${}^{0}F_T$ with phase φ_T. As described in Section 14.2.1, the normal scattering factor f^0 is strongly dependent on scattering angle, whereas f' and f'' are nearly invariant with s.

A very useful observational equation is obtained by applying the law of cosines to ${}^{0}F_T$, ${}^{\lambda}F'_A$ and ${}^{\lambda}F''_A$ (Karle, 1980; Hendrickson, 1985). Anomalous structure factors are treated separately for each kind of anomalous scatterer. The number of terms in the resulting expression is $(q+1)^2$ for q kinds of anomalous scatterers. For the commonest case of one kind of anomalous scatterer

$$ \begin{aligned} |{}^{\lambda}F_{\rm obs}(\pm\mathbf{h})|^2 &= |{}^{0}F_T|^2 + a_{\lambda}|{}^{0}F_A|^2 \\ &\quad + b_{\lambda}|{}^{0}F_T|\,|{}^{0}F_A|\cos(\varphi_T - \varphi_A) \\ &\quad \pm c_{\lambda}|{}^{0}F_T|\,|{}^{0}F_A|\sin(\varphi_T - \varphi_A), \end{aligned} \qquad (14.2.2.8) $$

where $a_{\lambda} = (f''^2_{\lambda} + f'^2_{\lambda})/(f^0)^2$, $b_{\lambda} = 2f'_{\lambda}/f^0$ and $c_{\lambda} = 2f''_{\lambda}/f^0$. $|{}^{\lambda}F_{\rm obs}(\pm\mathbf{h})|$ refers to the Bijvoet mate reflections $+\mathbf{h}$ and $-\mathbf{h}$. The MAD observational equation illustrates the orthogonal contributions to phasing made by the real (f') and imaginary (f'')

components of anomalous scattering. 'Dispersive' phase information derives from differences between $|F_{\rm obs}|$ at wavelengths having different values of f' and contributes to $\cos(\varphi_T - \varphi_A)$. 'Bijvoet' phase information derives from the Friedel difference $|F_{\rm obs}(+\mathbf{h})| - |F_{\rm obs}(-\mathbf{h})|$ at a wavelength with substantial f'' and contributes to $\sin(\varphi_T - \varphi_A)$. Phase information is enhanced by selection of wavelengths for data measurement that maximize the magnitudes of both f' and f''. Apart from ignoring the very weakest anomalous-scattering effects, the MAD observational equation (14.2.2.8) involves no approximations.

14.2.3. Diffraction ratios for estimating the MAD phasing signal

The first consideration in design of a MAD experiment is the choice of anomalous scatterer(s) with consideration of the magnitude of the phasing signal. Estimation of the total scattering by the macromolecule and the potential phasing signal generated by the anomalous scatterer(s) under consideration is informative.

The magnitude of the MAD phasing signal is estimated as the ratio of the expected dispersive or Bijvoet difference to the expected total scattering of the macromolecule. This is based on calculation of the expected root-mean-square structure amplitude (rms$|F|$) (Wilson, 1942),

$$\mathrm{rms}|F| = \langle |F|^2 \rangle^{1/2} = \left(\textstyle\sum f_i^2\right)^{1/2} = N^{1/2} f \qquad (14.2.3.1)$$

for N identical atoms. The expected total scattering of the macromolecule is estimated at $s = 0$ using an average non-hydrogen atom. Based on atomic frequencies in biological macromolecules, the average values of f^0 are 6.70 e for proteins, 7.20 e for DNA and 7.26 e for RNA. The average number of non-hydrogen atoms and molecular mass per residue are 7.7 atoms and 110 Da for proteins, 21.8 atoms and 292 Da for DNA, and 22.4 atoms and 304 Da for RNA. These averages result in the following expressions for estimated total scattering of biological macromolecules:

$$\begin{aligned}
\mathrm{rms}|^0F_T|_{\rm protein} &\approx 6.70(\text{No. of atoms})^{1/2} \approx (346 \times \text{No. of amino acids})^{1/2}\\
&\approx (3.14 \times \text{molecular mass})^{1/2}\\
\mathrm{rms}|^0F_T|_{\rm DNA} &\approx 7.20(\text{No. of atoms})^{1/2} \approx (1128 \times \text{No. of nucleotides})^{1/2}\\
&\approx (3.87 \times \text{molecular mass})^{1/2}\\
\mathrm{rms}|^0F_T|_{\rm RNA} &\approx 7.26(\text{No. of atoms})^{1/2} \approx (1183 \times \text{No. of nucleotides})^{1/2}\\
&\approx (3.89 \times \text{molecular mass})^{1/2}. \qquad (14.2.3.2)
\end{aligned}$$

Note: the estimated total scattering of a protein is coincidentally $\approx (\pi \times \text{molecular mass})^{1/2}$.

The diffraction ratios relevant to a MAD experiment with N anomalous-scatterer sites are

$$\frac{\mathrm{rms}\big||^{\lambda1}F_{\rm obs}| - |^{\lambda2}F_{\rm obs}|\big|}{\mathrm{rms}|^0F_T|} \approx (N/2)^{1/2}\,\frac{|f'_{\lambda1} - f'_{\lambda2}|}{\mathrm{rms}|^0F_T|} \qquad (14.2.3.3)$$

for the dispersive signal and

$$\frac{\mathrm{rms}\big||^{\lambda}F^+_{\rm obs}| - |^{\lambda}F^-_{\rm obs}|\big|}{\mathrm{rms}|^0F_T|} \approx (N/2)^{1/2}\,\frac{2f''_{\lambda}}{\mathrm{rms}|^0F_T|} \qquad (14.2.3.4)$$

for the Bijvoet signal. The diffraction ratios, analogous to similar relations for isomorphous replacement (Crick & Magdoff, 1956), are equivalent to the expected fractional changes in intensity due to anomalous scattering, and, as such, can be compared directly to the $R_{\rm sym}$ estimate of error in the experimental data for evaluation of the phasing signal. Of course, the phasing signal may be diminished by partial occupancy or thermal motion, as for normal scattering.

14.2.4. Experimental considerations

The design and execution of a MAD experiment are distinguished from monochromatic experiments in macromolecular crystallography primarily by the stringent criteria for wavelength selection.

The largest MAD phasing signal is obtained at energies with the most extreme values of f' and f'', which correspond to the sharpest features of the absorption edge (Fig. 14.2.1.1). The energy of peak absorption just above the edge ($E_{\rm peak}$) corresponds to the wavelength of maximum f'' and optimal Bijvoet signal ($\lambda_{\rm peak}$). Typically, the orthogonal dispersive signal is optimized by recording one data set at the wavelength corresponding to the inflection point of the absorption edge (minimum f', $\lambda_{\rm edge}$), and one or more data sets at remote wavelengths having f' with smaller magnitudes ($\lambda_{\rm remote}$). The choice of the remote wavelength(s) is experiment dependent. If only one remote wavelength is used, it is typically on the high-energy side of the absorption edge due to the larger Bijvoet signal. The remote wavelength(s) may also be chosen to avoid complications from other edges or to obtain data at a wavelength optimal for model refinement. In the case of anomalous scatterers that exhibit sharp 'white line' features, the dispersive signal may be optimized between the minimum of f' at the ascending edge ($\lambda_{\rm edge}$) and the local maximum of f' at the descending inflection point ($\lambda_{\rm descent}$).

The features of an X-ray absorption edge are in many cases very sharp, with the energies of the inflection point and peak absorption separated by as little as 2 eV. Therefore, it is critical to determine $\lambda_{\rm edge}$ and $\lambda_{\rm peak}$ experimentally by recording the absorption edge from the labelled macromolecule at the time of a MAD experiment. Even when the position of the edge is well known, small unanticipated chemical changes in the sample or calibration errors in the X-ray beam can reduce the MAD signal very significantly.

The MAD phasing signal is derived from intensity differences that may be similar in magnitude to measurement errors. Thus a general philosophy in the design of a MAD experiment is to equalize systematic errors among the measurements whose differences will contribute to each phase determination. This is achieved for each unique reflection by recording Bijvoet measurements at all wavelengths from the same asymmetric portion of diffraction space at nearly the same time. If crystal decay necessitates use of multiple crystals in a MAD experiment, blocks of Bijvoet data should be recorded identically at all of the selected wavelengths from each crystal contributing to the data set. Bijvoet mates can be recorded simultaneously by alignment of the crystal with a mirror plane of diffraction symmetry perpendicular to the rotation axis, or Friedel images can be recorded in an 'inverse beam' experiment. Inverse-beam geometry is a hypothetical method for measurement of Friedel data using both the forward and reverse directions of the incident X-ray beam. In a real experiment, diffraction images and their Friedel equivalents are recorded at crystal positions related by 180° rotation about any axis perpendicular to the incident beam, usually the data-collection axis. The inverse-beam experiment requires neither crystal symmetry nor crystal alignment, and is well suited to crystals mounted in random orientations.

The multiwavelength measurements for each unique reflection will be identically redundant and have nearly equal systematic errors if identical blocks of Bijvoet data are collected, as described above. When such a data-collection strategy is followed, the resulting MAD data set will include all multiwavelength Bijvoet measurements for all regions of the reciprocal lattice that are covered in the experiment.

Cryopreservation of crystals is of enormous benefit to MAD. Systematic error due to radiation damage is eliminated or greatly diminished. Systematic differences between crystals are eliminated in cases where a complete MAD data set is measured from a single frozen crystal. Intensities of weak reflections are estimated more accurately because less material contributes to diffuse background scatter in the mounts used for frozen crystals than for unfrozen crystals.

Measurement errors are of major importance in all areas of macromolecular crystallography, but are the limiting factor in phase determination by MAD. MAD data should be of high quality by the usual measures ($R_{\rm sym}$, redundancy, completeness), especially in experiments where the phasing signal is weak. Good counting statistics are of paramount importance. Experimental error, estimated by $R_{\rm sym}$, increases with increasing scattering angle because of the strong fall-off of f^0 with s. In a carefully designed experiment, the effect of increasing $R_{\rm sym}$ with s is mitigated somewhat by equalizing systematic errors and by averaging highly redundant data. Disappearance of the phasing signal into $R_{\rm sym}$ noise is the major reason that useful MAD phases are not obtained to the diffraction limit of crystals, even though anomalous scattering does not diminish with increasing s.

The optimal number of data-collection wavelengths for successful phase determination by MAD has been debated. In most cases, it is necessary to measure data at $\lambda_{\rm edge}$, $\lambda_{\rm peak}$ and a $\lambda_{\rm remote}$ in order to take advantage of the most extreme values of f' and f''. If f' values at $\lambda_{\rm edge}$ and $\lambda_{\rm peak}$ are different enough to produce a detectable dispersive signal, then phases can be obtained from three measurements: $|F^+|$ and $|F^-|$ at $\lambda_{\rm peak}$, and either $|F^+|$ or $|F^-|$ at $\lambda_{\rm edge}$. However, redundancy is one of the best ways to minimize the effects of measurement error in macromolecular crystallography. Redundant Bijvoet signals can be obtained at $\lambda_{\rm peak}$ and at any $\lambda_{\rm remote}$ above the absorption edge if both $|F^+|$ and $|F^-|$ are measured at each wavelength. Likewise, the dispersive signal between measurements at $\lambda_{\rm edge}$ and $\lambda_{\rm remote}$ is also redundant if both $|F^+|$ and $|F^-|$ measurements are taken at each wavelength. More highly redundant four- or five-wavelength MAD experiments may be advantageous, although greater redundancy should not be gained at the cost of good counting statistics. Brilliant synchrotron sources and high-speed detectors make rapid measurement of complete multiwavelength data sets possible, but the practical feasibility is often compromised by radiation damage. Phase information from the Bijvoet signal at a single wavelength (preferably $\lambda_{\rm peak}$) can also be used as a basis for structure determination. The phase probability distribution from single-wavelength anomalous scattering is in general bimodal, and must be resolved with additional phase information. This could be the partial structure of anomalous scatterers, as in the classic crambin experiment (Hendrickson & Teeter, 1981), or the real-space constraints, such as solvent flattening or redundancy averaging, that are applied in common schemes for phase refinement by density modification.

14.2.5. Data handling

Two general approaches to data handling for MAD have been employed.

An extreme interpretation of the scheme for equalizing systematic errors is known as 'phase first, merge later' (Hendrickson, 1985; Hendrickson & Ogata, 1997). The idea is that systematic errors may be amplified by merging data, and that this may obscure a weak phasing signal. In this approach, the individual observations constituting a multiwavelength Bijvoet set, as determined by the data-collection strategy, are grouped together and scaled. There may be redundant multiwavelength sets of observations, but these are merged only after individual phase evaluations have been made. Error estimates from the phasing, or the agreement of redundant phase determinations, can be incorporated into weights for averaging, or can be used to reject outliers. Complicated, experiment-dependent bookkeeping is required to assemble exactly the correct observations into each unmerged set of multiwavelength measurements. However, the 'phase first, merge later' approach may be advantageous for MAD data sets from multiple crystals, or when minor disasters disrupt the experiment and thwart the data-collection strategy.

A second approach, known as 'merge first, phase later', is to scale and merge data at each wavelength, keeping Bijvoet pairs separate, and then to scale data at all wavelengths to one another (Ramakrishnan & Biou, 1997). The idea is that the multiwavelength Bijvoet measurements are identically redundant for each unique reflection if the MAD data were measured according to the strategy outlined in Section 14.2.4. Thus, merging the redundancies should reduce systematic errors in the amplitude differences used for phasing. The 'merge first, phase later' approach is computationally simpler than the 'phase first, merge later' approach because it is experiment independent. However, unanticipated experimental disasters may be more difficult to overcome in the 'merge first, phase later' approach to data handling.

Of course, if the MAD signal is strong relative to the experimental error, either approach to data handling should be successful. Data scaling in both approaches may be done most easily and reliably by scaling all data against a standard data set, such as the unique data from one wavelength with Bijvoet mates averaged. In general a dogmatic approach to data handling is best avoided in favour of whichever computational technique or combination of techniques is most suited to the problem at hand. Factors such as the strength of the MAD signal, data-collection strategy, number of crystals contributing to the data set, crystal quality and experimental disasters should be taken into account.

14.2.6. Approaches to MAD phasing

There are two general approaches to MAD phasing. In the explicit approach, the MAD observational equation is solved directly (Hendrickson *et al.*, 1988; Hendrickson & Ogata, 1997). In the pseudo-MIR approach, MAD phasing is treated as a special case of multiple isomorphous replacement (Burling *et al.*, 1996; Terwilliger, 1997; Ramakrishnan & Biou, 1997). Both approaches have been quite successful, and each has advantages and disadvantages. For complete phase determination by either method, the partial structure of the anomalous scatterers must be determined. The explicit and pseudo-MIR approaches differ in when the partial structure is determined and in how it is refined.

The explicit approach provides the quantities $|{}^0F_T|$, $|{}^0F_A|$ and $(\varphi_T - \varphi_A)$ by direct fit of the $|{}^\lambda F_{\rm obs}|$ to the MAD observational equation (14.2.2.8). No anomalous-scatterer partial structure model is required in this first step of phasing. Estimates of the anomalous scattering factors at the wavelengths of data collection are required. These estimates can be refined (Weis *et al.*, 1991), so they need not be highly accurate. Redundancies are merged to produce a unique data set at the level of the derived quantities $|^0F_T|$, $|^0F_A|$, $(\varphi_T - \varphi_A)$ and their error estimates. The anomalous-scatterer partial structure is determined from the derived estimates of $|^0F_A|$ and refined against these amplitudes. In the second step of phasing, φ_T is derived from the phase difference $(\varphi_T - \varphi_A)$ and weights are calculated for a Fourier synthesis from $|^0F_T|$ and φ_T. Phase probability distributions (*ABCD* coefficients; Hendrickson & Lattman, 1970) derived from the MAD observational equation (14.2.2.8) can be used directly in the explicit approach (Pähler *et al.*, 1990). A probabilistic treatment based on maximum likelihood theory has also been developed (de La Fortelle & Bricogne, 1997). There are two advantages to the explicit approach. First, it is amenable to the 'phase first, merge later' scheme of data handling because refinement of the anomalous-scatterer partial structure is entirely separate from phase calculation. The second principal advantage of the explicit approach is the calculation of an experimentally derived estimate of the normal structure amplitude $|^0F_A|$ for the anomalous scatterer. This is the quantity with which the partial structure of anomalous scatterers is most directly solved and refined. However, extraction of reliable $|^0F_A|$ estimates from data with low signal-to-noise can be difficult. Bayesian methods of $|^0F_A|$ estimation (Terwilliger, 1994; Krahn *et al.*, 1999) have been shown to be more robust than least-squares methods.

In the pseudo-MIR approach, data at one wavelength are designated as 'native' data, which include anomalous scattering, and data at the other wavelengths as 'derivative' data. This approach has the advantage that nothing need be known about the anomalous scattering factors at any time during phasing. These quantities are incorporated into heavy-atom atomic 'occupancies' and refined along with other parameters. Of course, the partial structure of anomalous scatterers must be known, and its refinement is concurrent with phasing. This may be a principal advantage of the pseudo-MIR approach, because the anomalous-scatterer parameter refinement may be more reliable when incorporated into phasing than when done against $|^0F_A|$ estimates. Greater weight is given to the data set selected as 'native' in refinement of the 'heavy-atom' parameters in some implementations of the pseudo-MIR approach, although others treat data at all wavelengths equivalently (Terwilliger & Berendzen, 1997). The amplitudes $|^0F_A|$ are not a by-product of the pseudo-MIR approach.

14.2.7. Determination of the anomalous-scatterer partial structure

Determination of the partial structure of anomalous scatterers is a prerequisite for MAD-phased electron density, regardless of the phasing technique. As described above, the optimal quantities for solving and refining the partial structure of anomalous scatterers are the normal structure amplitudes $|^0F_A|$. Frequently $|^0F_A|$ values are not extracted from the MAD measurements, and the largest Bijvoet or dispersive differences are used instead. This involves the approximation of representing structure amplitudes $(|^0F_A|)$ as the subset of larger differences $(||F^+| - |F^-||$ or $||F_{\lambda^1}| - |F_{\lambda^2}||)$. The approximation is accurate for only a small fraction of reflections because there is little correlation between φ_A and φ_T. However, it suffices for a suitably strong signal and a suitably small number of sites. Patterson methods are quite successful in locating anomalous scatterers when the number of sites is small. However, the aim of MAD is to solve the macromolecule structure from one MAD data set using any number of anomalous scatterer sites. For larger numbers of sites, statistical direct methods may be employed.

The correct enantiomorph for the anomalous-scatterer partial structure also must be determined (φ_A *versus* $-\varphi_A$) in order to obtain an electron-density image of the macromolecule. However, it cannot be determined directly from MAD data. The correct enantiomorph is chosen by comparison of electron-density maps based on both enantiomorphs of the partial structure. Unlike the situation for pure MIR, the density based on the incorrect enantiomorph of the anomalous-scatterer partial structure is not the mirror image of that based on the correct enantiomorph and contains no image of the macromolecule. The correct map is distinguished by features such as a clear solvent boundary, positive correlation of redundant densities and a macromolecule-like density histogram. If the anomalous-scattering centres form a centric array, then the two enantiomorphs are identical and both maps are correct.

14.2.8. General anomalous-scatterer labels for biological macromolecules

MAD requires a suitable anomalous scatterer, of which none are generally present in naturally occurring proteins or nucleic acids. However, selenomethionine (SeMet) substituted for the natural amino acid methionine (Met) is a general anomalous-scattering label for proteins (Hendrickson, 1985), and is the anomalous scatterer most frequently used in MAD. The *K* edge of Se is the most accessible for MAD experiments ($\lambda = 0.98$ Å).

The SeMet label is especially general and convenient because it is introduced by biological substitution of SeMet for methionine. This is achieved by blocking methionine biosynthesis and substituting SeMet for Met in the growth medium of the cells in which the protein is produced. Production of SeMet protein in bacteria is generally straightforward (Hendrickson *et al.*, 1990; Doublié, 1997) and has also been accomplished in eukaryotic cells (Lustbader *et al.*, 1995; Bellizzi *et al.*, 1999).

Methionine is a particularly attractive target for anomalous-scatterer labelling because the side chain is usually buried in the hydrophobic core of globular proteins where it is relatively better ordered than are surface side chains. The labelling experiment provides direct evidence for isostructuralism of Met and SeMet proteins. All proteins in the biological expression system have SeMet substituted for Met at levels approaching 100%. The cells are viable, therefore the proteins are functional and isostructural with their unlabelled counterparts to the extent required by function.

The natural abundance of methionine in soluble proteins is approximately one in fifty amino acids, providing a typical MAD phasing signal of 4–6% of $|F|$ [equations (14.2.3.3) and (14.2.3.4)]. Typical extreme values for the anomalous scattering factors are $f'_{\rm min} \sim -10$ e and $f''_{\rm max} \sim 6$ e (Fig. 14.2.1.1). SeMet is more sensitive to oxidation than is Met, and care must be taken to maintain a homogeneous oxidation state. Generally, the reduced state is maintained by addition of disulfide reducing agents to SeMet protein and crystals. However, the oxidized forms of Se have sharper *K*-edge features and f' and f'' values of greater magnitude than does the reduced form (Smith & Thompson, 1998). This property has been exploited to enhance anomalous signals by intentional oxidation of SeMet protein (Sharff *et al.*, 2000). SeMet is also a useful isomorphous-replacement label with a signal of ~10% of $|F|$. Prior knowledge of the sites of labelling is extremely useful during initial fitting of a protein sequence to electron density. Also, noncrystallographic symmetry operators can usually be defined more reliably from Se positions in SeMet protein than by heavy-atom positions in MIR due to the uniformity and completeness of labelling (Tesmer *et al.*, 1996).

An analogous general label is available for nucleic acids in the form of brominated bases, particularly 5-bromouridine, which is isostructural with thymidine. The *K* edge of Br corresponds to a wavelength of 0.92 Å, which is quite favourable for data collection.

Chapter 14.3. Automated MAD and MIR structure solution

T. C. Terwilliger and J. Berendzen

14.3.1. Introduction

In favourable cases, structure solution by X-ray crystallography using the multiwavelength anomalous diffraction (MAD) or multiple isomorphous replacement (MIR) methods can be a straightforward, though often lengthy, process. The recently developed *Solve* software (Terwilliger & Berendzen, 1999*b*) is designed to fully automate this class of structure solution. The overall approach is to link together all the analysis steps that a crystallographer would normally carry out into a seamless procedure, and in the process to convert each decision-making step into an optimization problem.

In the case of both MAD and MIR data, a key element of the procedure is the scoring and ranking of possible solutions. This scoring procedure makes it possible to treat structure solution as an optimization procedure, rather than a decision-making one. In the case of MAD data, a second key element of the procedure is the conversion of MAD data to a pseudo-SIRAS form (Terwilliger, 1994*b*) that allows much more rapid analysis than one involving the full MAD data set.

14.3.2. MAD and MIR structure solution

The MAD and MIR approaches to structure solution are conceptually very similar and share several important steps. Two of these are the identification of possible locations of heavy or anomalously scattering atoms and an analysis of the quality of each of these potential heavy-atom solutions. In each method, trial partial structures for these heavy or anomalously scattering atoms are often obtained by inspection of difference Patterson functions or by semi-automated analysis (*e.g.* Terwilliger *et al.*, 1987; Chang & Lewis, 1994; Vagin & Teplyakov, 1998). In other cases, direct-methods approaches have been used to find heavy-atom sites (Sheldrick, 1990; Miller *et al.*, 1994). Potential heavy-atom solutions found in any of these approaches are often just a starting point for structure solution, with additional sites found by difference Fourier or other approaches.

The analysis of the quality of potential heavy-atom solutions is also very similar in the MIR and MAD methods. In both cases a partial structure is used to calculate native phases for the entire structure, and the electron density that results is examined to see if the expected features of the macromolecule are found. Additionally, the agreement of the heavy-atom model with the difference Patterson function and the figure of merit of phasing are commonly used to evaluate the quality of a solution. In many cases, an analysis of heavy-atom sites by sequential deletion of individual sites or derivatives is often an important criterion of quality as well (Dickerson *et al.*, 1961).

14.3.3. Decision making and structure solution

The process of structure solution can be thought of largely as a decision-making process. In the early stages of solution, a crystallographer must choose which of several potential trial solutions may be worth pursuing. At a later stage, the crystallographer must choose which peaks in a heavy-atom difference Fourier are to be included in the heavy-atom model, and which hand of the solution is correct. At a final stage, the crystallographer must decide whether the solution process is complete and which of the possible heavy-atom models is the best. The most important feature of the *Solve* software is the use of a consistent scoring algorithm as the basis for making all these decisions.

14.3.4. The need for rapid refinement and phasing during automated structure solution

In order to make automated structure solution practical, it was necessary to be able to evaluate heavy-atom solutions very rapidly. This is because the automated approach used by *Solve* requires analysis of many heavy-atom solutions (typically 300–1000). For each heavy-atom solution examined, the heavy-atom sites have to be refined and phases calculated. In implementing automated structure solution, it was important to recognize the need for a trade-off between the most accurate heavy-atom refinement and phasing at all stages of structure solution and the time required to carry it out. The balance chosen for *Solve* was to use the most accurate available methods for final phase calculations, and to use approximate but much faster methods for all refinements and phase calculations. The refinement method chosen on this basis was origin-removed Patterson refinement (Terwilliger & Eisenberg, 1983), which treats each derivative in an MIR data set independently and which is very fast because it does not require phase calculation. The phasing approach used for MIR data thoughout *Solve* is Bayesian correlated phasing (Terwilliger & Berendzen, 1996; Terwilliger & Eisenberg, 1987), which takes into account the correlation of non-isomorphism among derivatives without substantially slowing down phase calculations.

For MAD data, Bayesian calculations of phase probabilities are very slow (*e.g.* Terwilliger & Berendzen, 1997; de La Fortelle & Bricogne, 1997). Consequently, we have used an alternative procedure for all MAD phase calculations except those done at the very final stage. This alternative is to convert the MAD data set into a form that is similar to one obtained in the single isomorphous replacement with anomalous scattering (SIRAS) method. In this way, a single data set with isomorphous and anomalous differences is obtained that can be used in heavy-atom refinement by the origin-removed Patterson refinement method and in phasing by conventional SIRAS phasing (Terwilliger & Eisenberg, 1987).

14.3.5. Conversion of MAD data to a pseudo-SIRAS form

The conversion of MAD data to a pseudo-SIRAS form that has almost the same information content requires two important assumptions. The first assumption is that the structure factor corresponding to anomalously scattering atoms in a structure varies in magnitude but not in phase at various X-ray wavelengths. This assumption will hold when there is one dominant type of anomalously scattering atom. The second is that the structure factor corresponding to anomalously scattering atoms is small compared to the structure factor from all other atoms. As long as these two assumptions hold, the information in a MAD experiment is largely contained in just three quantities: a structure factor (F_o) corresponding to the scattering from non-anomalously scattering atoms, a dispersive or isomorphous difference at a standard wavelength λ_o ($\Delta^{\rm ISO}_{\lambda_o}$), and an anomalous difference ($\Delta^{\rm ANO}_{\lambda_o}$) at the same standard wavelength (Terwilliger, 1994*b*). It is easy to see that these three quantities could be treated just like a SIRAS data set with the 'native' structure factor F_P replaced by F_o, the derivative structure factor F_{PH} replaced by $F_o + \Delta^{\rm ISO}_{\lambda_o}$, and the anomalous difference replaced by $\Delta^{\rm ANO}_{\lambda_o}$ (Terwilliger, 1994*b*). This is the approach taken by *Solve*. In this section, it is briefly shown how these three quantities can be estimated from MAD data.

For a particular reflection and a particular wavelength λ_j, we can write the total normal (*i.e.*, non-anomalous) scattering from a structure ($\mathbf{F}_{{\rm tot},\,\lambda_j}$) as the sum of two components. One is the scattering from all non-anomalously scattering atoms ($\mathbf{F}_o$). This scattering is wavelength-independent. The second is the normal scattering from anomalously scattering atoms ($\mathbf{F}_{H_{\lambda_j}}$) at wavelength λ_j. This term includes wavelength-dependent dispersive shifts in atomic scattering due to the f' term in the scattering factor, but not the anomalous part due to the f'' term. The magnitude of the total scattering factor can then be written in the form

$$F_{{\rm tot},\,\lambda_j} = |\mathbf{F}_o + \mathbf{F}_{H_{\lambda_j}}|. \tag{14.3.5.1}$$

Here $\mathbf{F}_o$ and $\mathbf{F}_{{\rm tot},\,\lambda_j}$ can be thought of corresponding, respectively, to the native structure factor, F_P, and the derivative structure factor, F_{PH}, as used in the method of isomorphous replacement (Blundell & Johnson, 1976). If the scattering from anomalously scattering atoms is small compared to that from all other atoms, equation (14.3.5.1) can be rewritten in the approximate form

$$F_{{\rm tot},\,\lambda_j} \simeq F_o + F_{H_{\lambda_j}} \cos(\alpha), \tag{14.3.5.2}$$

where α is the phase difference between the structure factors corresponding to non-anomalously and anomalously scattering atoms in the unit cell, $\mathbf{F}_o$ and $\mathbf{F}_{H_{\lambda_j}}$, respectively, at this X-ray wavelength.

The data in a MAD experiment consist of observations of structure-factor amplitudes for Bijvoet pairs, $F^+_{\lambda_j}$ and $F^-_{\lambda_j}$, for several X-ray wavelengths λ_j. These can be rewritten in terms of an average structure-factor amplitude $\overline{F}_{\lambda_j}$ and an anomalous difference $\Delta^{\rm ANO}_{\lambda_j}$ (*cf.* Blundell & Johnson, 1976). We would like to convert these into estimates of the amplitude of the structure factor corresponding to the non-anomalously scattering atoms alone, the amplitude of the structure factor corresponding to the entire structure at a standard wavelength, and the anomalous difference at the standard wavelength.

The normal scattering due to anomalously scattering atoms ($\mathbf{F}_{H_{\lambda_j}}$) changes in magnitude but not direction as a function of X-ray wavelength. We can therefore write (Terwilliger, 1994*b*)

$$\mathbf{F}_{H_{\lambda_j}} = \mathbf{F}_{H_{\lambda_o}} \frac{f_o + f'(\lambda_j)}{f_o + f'(\lambda_o)}, \tag{14.3.5.3}$$

where λ_o is an X-ray wavelength arbitrarily defined as a standard, and the real part of the scattering factor for the anomalously scattering atoms at wavelength λ_o is $f_o + f'(\lambda_j)$. A corresponding approximation for the anomalous differences at various wavelengths can also be written (Terwilliger & Eisenberg, 1987)

$$\Delta^{\rm ANO}_{\lambda_j} = \Delta^{\rm ANO}_{\lambda_o} \frac{f''(\lambda_j)}{f''(\lambda_o)}, \tag{14.3.5.4}$$

where $f''(\lambda_j)$ is the imaginary part of the scattering factor for the anomalously scattering atoms at wavelength λ_j. Based on equation (14.3.5.4), anomalous differences at any wavelength can be estimated using measurements at the standard wavelength.

An estimate of the structure-factor amplitude (F_o) corresponding to the scattering from non-anomalously scattering atoms and of the dispersive difference at standard wavelength λ_o ($\Delta^{\rm ISO}_{\lambda_o}$) can be obtained from average structure-factor amplitudes ($\overline{F}_{\lambda_j}$) at any pair of wavelengths λ_i and λ_j by proceeding in two steps. Using equations (14.3.5.2) and (14.3.5.3), the component of $\mathbf{F}_{H_{\lambda_o}}$ along $\mathbf{F}_o$, which we term $\Delta^{\rm ISO}_{\lambda_o}$, can be estimated as

$$\Delta^{\rm ISO}_{\lambda_o} \simeq F_{H_{\lambda_o}} \cos(\alpha) \tag{14.3.5.5}$$

or

$$\Delta^{\rm ISO}_{\lambda_o} \simeq (\overline{F}_{\lambda_i} - \overline{F}_{\lambda_j}) \frac{f_o + f'(\lambda_o)}{f'(\lambda_i) - f'(\lambda_j)}. \tag{14.3.5.6}$$

Then, in turn, this estimate of $\Delta^{\rm ISO}_{\lambda_o}$ can be used to obtain F_o:

$$F_o \simeq \overline{F}_{\lambda_j} - \Delta^{\rm ISO}_{\lambda_o} \frac{f_o + f'(\lambda_j)}{f_o + f'(\lambda_o)}. \tag{14.3.5.7}$$

This set of F_o, $F_o + \Delta^{\rm ISO}_{\lambda_o}$ and $\Delta^{\rm ANO}_{\lambda_j}$ can then be used just as F_P, F_{PH} and $\Delta^{\rm ANO}$ are used in the SIRAS (single isomorphous replacement with anomalous scattering) method.

The algorithm described above is implemented in the program segment *MADMRG* as part of *Solve* (Terwilliger, 1994*b*). In most cases, there are more than one pair of X-ray wavelengths corresponding to a particular reflection. The estimates from each pair of wavelengths are averaged, using weighting factors based on the uncertainties in each estimate. Data from various pairs of X-ray wavelengths and from various Bijvoet pairs can have very different weights in their contributions to the total. This can be understood by noting that pairs of wavelengths that yield a large value of the denominator in equation (14.3.5.6) (*i.e.*, those that differ considerably in dispersive contributions) would yield relatively accurate estimates of $\Delta^{\rm ISO}_{\lambda_o}$. In the same way, Bijvoet differences measured at the wavelength with the largest value of f'' will contribute the most to estimates of $\Delta^{\rm ANO}_{\lambda_j}$.

The standard wavelength choice in this analysis is arbitrary, because values at any wavelength can be converted to values at any other wavelength. The standard wavelength does not even have to be one of the wavelengths in the experiment, though it is convenient to choose one of them.

14.3.6. Scoring of trial heavy-atom solutions

Scoring of potential heavy-atom solutions is an essential part of the *Solve* algorithm because it allows ranking of solutions and appropriate decision making. *Solve* scores trial heavy-atom solutions (or anomalously scattering atom solutions) using four criteria: agreeement with the Patterson function, cross-validation of heavy-atom sites, figure of merit, and non-randomness of the electron-density map. The scores for each criterion are normalized to those for a group of starting solutions (most of which are incorrect) to obtain Z scores. The total score for a solution is the sum of its Z scores after correction for anomalously high scores in any category.

The first criterion used by *Solve* for evaluating a trial heavy-atom solution is the agreement between calculated and observed Patterson functions. Comparisons of this type have always been important in the MIR and MAD methods (Blundell & Johnson, 1976). The score for Patterson-function agreement is the average value of the Patterson function at predicted locations of peaks, after multiplication by a weighting factor based on the number of heavy-atom sites in the trial solution. The weighting factor (Terwilliger & Berendzen, 1999*b*) is adjusted so that if two solutions have the same mean value at predicted Patterson peaks, the one with the larger numbers of sites receives the higher score. Typically the weighting factor is approximately given by $(N)^{1/2}$, where there are N sites in the solution.

In some cases, predicted Patterson vectors fall on high peaks that are not related to the heavy-atom solution. To exclude these contributions, occupancies of each heavy-atom site are refined so that the predicted peak heights approximately match the observed peak heights at the predicted interatomic positions. Then all peaks with heights more than 1σ higher than their predicted values are truncated at this height. The average values are further corrected for instances where more than one predicted Patterson vector falls on the same location by scaling that peak height by the fraction of predicted vectors that are unique.

A 'cross-validation' difference Fourier analysis is the basis of the second criterion used to evaluate heavy-atom solutions. One at a time, each site in a solution (and any equivalent sites in other derivatives for MIR solutions) is omitted from the heavy-atom model and phases are recalculated. These phases are used in a difference Fourier analysis and the peak height at the location of the omitted site is noted. A similar analysis where a derivative is omitted from phasing and all other derivatives are used to phase a difference Fourier has been used for many years (Dickerson *et al.*, 1961). The score for cross-validation difference Fouriers is the average peak height, after weighting by the same factor used in the difference Patterson analysis.

The mean figure of merit of phasing (m) (Blundell & Johnson, 1976) can be a remarkably useful measure of the quality of phasing despite its susceptibility to systematic error (Terwilliger & Berendzen, 1999*b*). The overall figure of merit is essentially a measure of the internal consistency of the heavy-atom solution and the data, and is used as the third criterion for solution quality in *Solve*. As heavy-atom refinement in *Solve* is carried out using origin-removed Patterson refinement (Terwilliger & Eisenberg, 1983), occupancies of heavy-atom sites are relatively unbiased. This minimizes the problem of high occupancies leading to inflated figures of merit. Additionally, using a single procedure for phasing allows comparison between solutions. The score based on figure of merit is simply the unweighted mean for all reflections included in phasing.

The most important criterion used by a crystallographer in evaluating the quality of a heavy-atom solution is the interpretability of the resulting electron-density map. Although a full implementation of such a criterion is difficult, it is quite straightforward to evaluate instead whether the electron-density map has features that are expected for a crystal of a macromolecule. A number of features of electron-density maps could be used for this purpose, including the connectivity of electron density in the maps (Baker *et al.*, 1993), the presence of clearly defined regions of protein and solvent (Wang, 1985; Podjarny *et al.*, 1987; Zhang & Main, 1990; Xiang *et al.*, 1993; Abrahams *et al.*, 1994; Terwilliger & Berendzen, 1999*a*,*c*), and histogram matching of electron densities (Zhang & Main, 1990; Goldstein & Zhang, 1998). We have used the identification of solvent and protein regions as the measure of map quality in *Solve*. This requires that there be both solvent and protein regions in the electron-density map, but for most macromolecular structures the fraction of the unit cell that is occupied by the macromolecule is in the suitable range of 30–70%. The criterion used in scoring by *Solve* is based on the connectivity of the solvent and protein regions (Terwilliger & Berendzen, 1999*c*). The unit cell is divided into boxes approximately twice the resolution of the map on a side, and within each box the r.m.s. electron density is calculated, without including the F_{000} term in the Fourier synthesis. For boxes within the protein region, this r.m.s. electron density will typically be high (as there are some points where atoms are located and other points between atoms), while for those in the solvent region it will be low (as the electron density is fairly uniform). The score based on the connectivity of the protein and solvent regions is simply the correlation coefficient of this r.m.s. electron density for adjacent boxes. If there is a large contiguous protein region and a large contiguous solvent region, then adjacent boxes will have highly correlated values of their r.m.s. electron densities. If the electron density is random, there will be little or no correlation. In practice, for a very good electron-density map, this correlation of local r.m.s. electron density may be as high as 0.5 or 0.6.

14.3.7. Automated MIR and MAD structure determination

The four-point scoring scheme described above provides the foundation for automated structure solution. To make it practical, the conversion of MAD data to a pseudo-SIRAS form and the use of rapid origin-removed Patterson-based heavy-atom refinement has been nearly essential. The remainder of the *Solve* algorithm for automated structure solution is largely a standardized form of local scaling, an integrated set of routines to carry out all of the calculations required for heavy-atom searching, refinement and phasing, and routines to keep track of the lists of current solutions being examined and past solutions that have already been tested.

Scaling of data in the *Solve* algorithm is done by a local scaling procedure (Matthews & Czerwinski, 1975). Systematic errors are minimized by scaling F^+ and F^-, native and derivative, and wavelengths of MAD data in very similar ways and by keeping different data sets separate until the end of scaling. The scaling procedure is optimized for cases where the data are collected in a systematic fashion. For both MIR and MAD data, the overall procedure is to construct a reference data set that is as complete as possible and that contains information either from a native data set (for MIR) or for all wavelengths (for MAD data). This reference data set is constructed for just the asymmetric unit of data and is essentially the average of all measurements obtained for each reflection. The reference data set is then expanded to the entire reciprocal lattice and used as the basis for local scaling of each individual data set [see Terwilliger & Berendzen (1999*b*) for additional details].

Once MIR data have been scaled, or MAD data have been scaled and converted to a pseudo-SIRAS form, difference Patterson functions are used to identify plausible one-site or two-site heavy-atom solutions. For MIR data, difference Patterson functions are calculated for each derivative. For MAD data, anomalous and dispersive differences are combined to yield a Bayesian estimate of the Patterson function for the anomalously scattering atoms (Terwilliger, 1994*a*). An automated search of the Patterson function is then used to find a large number (typically 30) of potential single-site and two-site solutions. In principle, Patterson methods could be used to solve the complete heavy-atom substructure, but the approach used in *Solve* is to find just the first one or two heavy-atom sites in this way and to find all others by difference Fourier analysis. This initial set of one-site and two-site solutions becomes the initial list of potential solutions ('seeds') for automated structure solution. Once each of the potential seeds is scored and ranked, the top seeds (typically five) are selected as independent starting points for the search for heavy-atom solutions.

For each starting solution (seed), the main cycle in the automated structure-solution algorithm used by *Solve* consists of two basic steps. The first is to refine heavy-atom parameters and rank all existing solutions generated so far from this seed based on the four criteria discussed above. The second is to take the highest-ranking solution that has not yet been exhaustively analysed and use it in an attempt to generate a more complete solution. Generation of new solutions is carried out in three ways: by deletion of sites, by addition of sites from difference Fouriers and by inversion. A partial solution is considered to have been exhaustively analysed when all single-site deletions have been considered, when no more peaks in a difference Fourier can be found that improve upon it, and when inversion does not improve it, or when the maximum number of sites input by the user has been reached. In each case, new solutions generated in these three ways are refined, scored and ranked, and the cycle is continued until all the top solutions have been fully analysed and no new solutions are found. Throughout this process, a tally of the solutions that have already been considered is kept, and any time a solution is a duplicate of a previously examined solution it is dropped.

In some cases, one very clear solution appears early in the structure-solution process, while in others, there are several solutions that have similar scores at early (and sometimes even late) stages of structure solution. In cases where no one solution is much better than the others, all the seeds are exhaustively analysed. On the other hand, if a very promising solution emerges from one seed, then the search is narrowed to focus on that seed, deletions are not carried out until the end of the analysis, and many peaks from the difference Fourier analysis are added at a time so as to build up the solution as quickly as possible. Once the expected number of heavy-atom sites are found, then each site is deleted in turn to see if the solution can be further improved. If this occurs, then the new solutions are analysed in the same way by addition and deletion of sites and by inversion until no improvement is obtained.

At the conclusion of the *Solve* algorithm, an electron-density map and phases for the top solution are reported in a form that is compatible with the *CCP4* suite (Collaborative Computational Project, Number 4, 1994). Additionally, command files that can be modified to look for additional heavy-atom sites or to construct other electron-density maps are produced. If more than one possible solution is found, the heavy-atom sites and phasing statistics for all of them are reported.

14.3.8. Generation of model X-ray data sets

An important feature of *Solve* is the inclusion of modules for the generation of model data. *Solve* can construct model raw X-ray data for either MIR or MAD cases. The macromolecular structure can be defined by a file in PDB format (Bernstein *et al.*, 1977) with heavy-atom parameters defined by the user. Any degree of 'experimental' uncertainty in measurement of intensities can be included, and limited non-isomorphism for MIR data in which cell dimensions differ for native and any of the derivative data sets (but in which the macromolecular structure is identical) can be included. This automatic generation of model data is very useful in evaluating what can and what cannot be solved. Once a data set has been generated, the *Solve* algorithm can be used to attempt to solve it. *Solve* generates a model electron-density map based on the input coordinates, and during the structure-solution process all maps calculated with trial solutions can be compared to the model map. In many cases, heavy-atom solutions can be related to different origins (and to different handedness as well). The origin shift is identified by *Solve* by finding the shift that best maps the trial solution onto the (known) correct solution.

14.3.9. Conclusions

The *Solve* algorithm is very useful for solving macromolecular structures by the MIR and MAD methods. It has been used to solve MAD structures with as many as 56 selenium atoms in the asymmetric unit (W. Smith & C. Janson, personal communication). From the user's point of view, the algorithm is very simple. Only a few input parameters are needed in most cases, and the *Solve* algorithm carries out the entire process automatically. In principle, the procedure can be very thorough as well, so that many trial starting solutions can be examined and difficult heavy-atom structures can be found. Additionally, for the most difficult structure-solution cases, the failure to find a solution can be useful in confirming that additional information is needed.

14.3.10. Software availability

The *Solve* software and complete documentation can be obtained from the web site http://solve.lanl.gov/.

PART 15. DENSITY MODIFICATION AND PHASE COMBINATION

Chapter 15.1. Phase improvement by iterative density modification

K. Y. J. Zhang, K. D. Cowtan and P. Main

15.1.1. Introduction

Density modification is a technique for improving the quality of an approximate electron-density map based on some conserved features of the correct electron-density map. These conserved features are independent of the unknown fine detail of the structural conformation. They are often expressed as constraints on the electron density in various forms, either in real or reciprocal space. Since the structure-factor amplitudes are known, these constraints restrict the values of phases and can therefore be used for phase improvement.

The structure-factor amplitudes and phases are independent of each other if we know nothing about the electron density. Therefore, the phases are indeterminable given only the amplitudes (Baker, Krukowski & Agard, 1993). The information about the electron density provides the missing link between structure-factor amplitudes and phases. It is only through the knowledge of the chemical or physical properties of the electron density that the phases can be retrieved. Density modification is usually the most straightforward application of the constraints on electron density. However, this is only a matter of convenience in implementation. Sometimes the constraints can be more readily implemented in reciprocal space on structure factors.

Density-modification methods are usually implemented as an iterative procedure that alternates between density modification in real space and phase combination in reciprocal space. This paradigm was first proposed by Hoppe & Gassmann (1968) in their 'phase correction' method. This approach takes advantage of the particular properties of the constraints and uses them in a way that is most convenient to implement.

Density-modification methods usually require an initial map with substantial phase information. In most cases, these phases are obtained from multiple isomorphous replacement (MIR) or multiwavelength anomalous dispersion (MAD), but it is also possible to improve maps from other sources, such as molecular replacement. The amount of information in the initial map is dependent on phase accuracy, data resolution and completeness. As more powerful constraints are incorporated, the density modification can be initiated from lower-resolution maps with less accurate phases. *Ab initio* phasing would be achieved if a density-modification method could start from a map generated from random phases. Therefore, density modification can potentially lead to *ab initio* phasing methods, although it does not seek direct solution to the phase problem as its immediate goal.

There are two major components in a density-modification procedure. One is the type of electron-density constraints. The other is the way the constraints are exploited. These two components combined determine the phasing power of the procedure. In this chapter, we will review various electron-density constraints and the way they are exploited for phase improvement.

15.1.2. Density-modification methods

The aim of density-modification calculations is to obtain new or improved phase estimates for observed structure-factor amplitudes. Often, this includes calculation of phases for previously unphased reflections, for example, in the case of phase extension. The calculation of weights, which indicate the degree of confidence in the new phase estimates, is also an important part of the calculation. Improved phase estimates are obtained by bringing the initial phase estimates into consistency with additional sources of structural information.

One difficulty in combining information from various sources is that the amplitudes and phases are represented in reciprocal space and include good estimates of error, whereas the other constraints are in real space and in general, represent expectations about the structure which may be hard to quantify. As a result, the method that has been adopted is iterative and divided into real- and reciprocal-space steps. A weighted map is calculated and used as a basis for applying all the real-space modifications. The modified map is then back-transformed to produce a set of amplitudes and phases. The agreement between the observed amplitudes and the amplitudes calculated from the modified map is then used to estimate weights for the modified phases, which are used to combine the modified phases with experimental phases to produce new phases. This process is shown diagrammatically in Fig. 15.1.2.1.

A broad range of techniques have been applied to electron-density maps to impose chemical or physical information. Some sources of information used in density modification are summarized in Table 15.1.2.1. The list included here is not exhaustive, but covers the most widely used methods. Here, we describe some of the constraints and the techniques through which these constraints are implemented for phase improvement.

Table 15.1.2.1
Constraints used in density modification

Constraints	Use	Effectiveness and limitation
(1) Solvent flatness	Solvent flattening	Works best at medium resolution. Relatively resolution insensitive. Good for phase refinement. Weak on phase extension.
(2) Ideal electron-density distribution	Histogram matching	Works at a wide range of resolutions. More effective at higher resolution. Very effective for phase extension.
(3) Equal molecules	Molecular averaging	Works better at low to medium resolution. Its phasing power increases with the number of molecules in the asymmetric unit.
(4) Protein backbone connectivity	Skeletonization	Requires near atomic resolution to work.
(5) Local shape of electron density	Sayre's equation	The equation is exact at atomic resolution. It can be used at non-atomic resolution by choosing an appropriate shape function. Its phasing power increases quickly with resolution. Very powerful for phase extension.
(6) Atomicity	Atomization	If the initial map is good enough, iteration could lead to a final model.
(7) Structure-factor amplitudes	Sim weighting	Can be used to estimate the reliability of the calculated phases after density modification. It assumes the random distribution of errors that caused the discrepancy between the calculated and observed structure-factor amplitudes.
(8) Experimental phases	Phase combination	This can be used to filter out the incorrect component of the estimated phases. Most phase-combination procedures assume independence between the calculated and observed phases.

15.1.2.1. Solvent flattening

Solvent flattening exploits the fact that the electron density in the solvent region is flat at medium resolution, owing to the high thermal motion and disorder of solvent molecules. The flattening of the solvent region suppresses noise in the map and therefore improves phases.

15.1.2.1.1. Introduction

Biological molecules are typically irregular in shape, often taking roughly globular forms. When they are packed regularly to form a crystal lattice, there are gaps left between them, and these spaces are filled with the solvent in which the crystallization was performed. This solvent is a disordered liquid, and thus the arrangement of atoms in the solvent regions varies between unit cells, except in those small regions near the surface of the protein. The X-ray image forms an average of electron density over many cells, so the electron density over much of the solvent region appears to be constant to a good approximation.

The existence of a flat solvent region in a crystal places strong constraints on the structure-factor phases. The constraint of solvent flatness is implemented by identifying the molecular boundaries and replacing the densities in the solvent region by their mean density value.

When solving a structure, the contents of the unit cell are usually known, and so an estimate can be formed of how much of the cell volume is taken up by solvent (Matthews, 1968). If the solvent region can be located in the cell, then we can improve an electron-density map by setting the electron density in this region to the expected constant solvent density. Once the resulting modified phases are combined with the experimental data, an improvement can often be seen in the protein regions of the map (Bricogne, 1974).

The solvent region of a unit cell may usually be determined even from a poor MIR map using the following features:

(1) The mean electron density in the solvent region should be lower than that in the protein region. Note that this information will come from the low-resolution data, which dictate long-range density variations over the unit cell.
(2) The variation in density in the flat solvent region should be much smaller than that in the ordered protein region containing isolated clumps of density. The 'peakiness' of the protein region comes from the high-resolution data.

A good method for locating the solvent region therefore takes into account information from both low- and high-resolution structure factors. Many methods have been proposed to locate the protein–solvent boundary. The first of these were the visual identification methods. The boundary was identified by digitizing a mini-map with the aid of a graphic tablet (Hendrickson *et al.*, 1975; Schevitz *et al.*, 1981). The hand-digitizing procedure was very time consuming and prone to subjective judgmental errors. Nevertheless, these methods demonstrated the potential of solvent flattening and stimulated further improvement on boundary-identification methods. An automated method using a linked, high-density approach was first proposed by Bhat & Blow (1982). Based on the fact that the densities are generally higher in the protein region than in the solvent region, they defined the molecular boundary by locating the protein as a region of linked, high-density points.

Convolution techniques were subsequently adopted as an efficient method of molecular-boundary identification. Reynolds *et al.* (1985) proposed a high mean absolute density value approach. The electron density within the protein region was expected to have greater excursions from the mean density value than the solvent region, which is relatively featureless. The molecular boundary was located based on the value of a smoothed ‘modulus’ electron density, which is the sum of the absolute values of all density points within a small box.

15.1.2.1.2. The automated convolution method for molecular-boundary identification

Wang (1985) suggested an automated convolution method for identifying the solvent region which has achieved widespread use. His method involved first calculating a truncated map:

$$\rho_{\rm trunc}(\mathbf{x}) = \begin{cases} \rho\mathbf{x}, & \rho(\mathbf{x}) > \rho_{\rm solv} \\ 0, & \rho(\mathbf{x}) < \rho_{\rm solv} \end{cases}. \qquad (15.1.2.1)$$

The electron density is simply truncated at the expected solvent value, $\rho_{\rm solv}$; however, since the variations in density in the protein region are much larger than the variations in the solvent region, it is generally only the protein region which will be affected. Thus, the mean density over the protein region is increased. Similar results may be obtained using the mean-squared difference of the density from the expected solvent value.

A smoothed map is then formed by calculating at each point in the map the mean density over a surrounding sphere of radius R. This operation can be written as a convolution of the truncated map, $\rho_{\rm trunc}$, with a spherical weighting function, $w(\mathbf{r})$,

$$\rho_{\rm ave}(\mathbf{x}) = \sum_{\mathbf{r}} {\rm w}(\mathbf{r})\rho_{\rm trunc}(\mathbf{x}-\mathbf{r}), \qquad (15.1.2.2)$$

where

$$w(\mathbf{r}) = \begin{cases} 1 - |\mathbf{r}|/R, & |\mathbf{r}| < R \\ 0, & |\mathbf{r}| > R \end{cases}. \qquad (15.1.2.3)$$

Leslie (1987) noted that the convolution operation required in equation (15.1.2.2) can be very efficiently performed in reciprocal space using fast Fourier transforms (FFTs),

$$\rho_{\rm ave}(\mathbf{x}) = \mathcal{F}^{-1}\{\mathcal{F}[\rho_{\rm trunc}(\mathbf{x})]\mathcal{F}[w(\mathbf{r})]\}, \qquad (15.1.2.4)$$

where $\mathcal{F}$ denotes a Fourier transform, and $\mathcal{F}^{-1}$ represents an inverse Fourier transform.

The Fourier transform of the truncated density can be readily calculated using FFTs. The Fourier transform of the weighting function can be calculated analytically by

$$g(s) = \mathcal{F}[w(\mathbf{r})] = \frac{3[\sin(2\pi Rs) - 2\pi Rs\cos(2\pi Rs)]}{(2\pi Rs)^3} - \frac{3\{4\pi Rs\sin(2\pi Rs) - [(2\pi Rs)^2 - 2]\cos(2\pi Rs) - 2\}}{(2\pi Rs)^4}, \qquad (15.1.2.5)$$

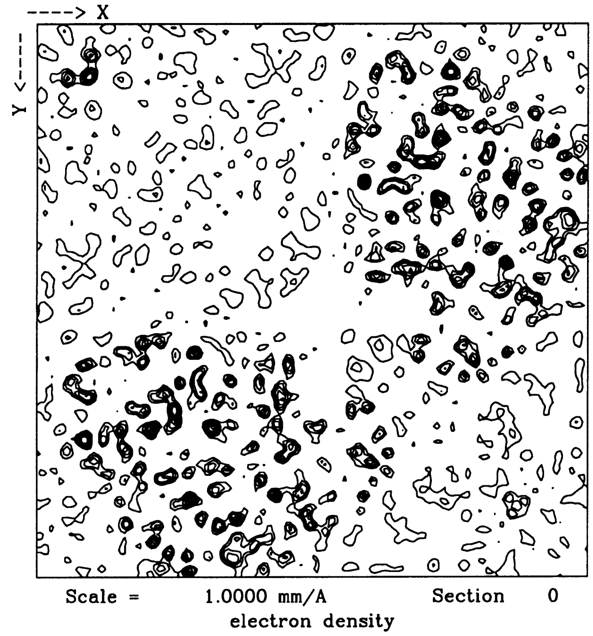
where

$$s = 2\sin\theta/\lambda.$$

Therefore, the averaging of the truncated electron density by a spherical weighting function can be achieved by two FFTs. This greatly reduced the time required for calculating the averaged density. Other weighting functions may be implemented by the same approach.

A cutoff value, $\rho_{\rm cut}$, is then calculated, which divides the unit cell into two portions occupying the correct volumes for the protein and solvent regions. All points in the map where $\rho_{\rm ave}(\mathbf{x}) < \rho_{\rm cut}$ can then be assumed to be in the solvent region. A typical mask obtained from an MIR map by this means, and the modified map, are shown in Fig. 15.1.2.2.

The radius of the sphere, R, used in equation (15.1.2.3) for the averaging of electron densities is generally around 8 Å. The molecular envelope derived from such an averaged map tends to lose details of the protein molecular surface. Paradoxically, a large averaging sphere is required for the identification of the protein–solvent boundary based on the difference between the mean density of the protein and solvent, which is very small and can only be distinguished when a sufficiently large area of the map is averaged. Abrahams & Leslie (1996) proposed an alternative method of molecular-boundary identification that uses the standard deviation of the electron density within a given radius relative to the overall mean at every grid point of a map. The local-standard-deviation map is the square root of a convolution of a sphere and the squared map, which can be calculated in reciprocal space in a similar way to the procedure described in equations (15.1.2.4) and (15.1.2.5) as proposed by Leslie (1987). By integrating the histogram of the local-standard-deviation map, the cutoff value of the local standard deviation corresponding to the solvent fraction can be calculated. Using this procedure, a molecular envelope that contains more details of the protein molecular surface can be obtained, since the radius of the averaging sphere can be as low as 4 Å (Abrahams & Leslie, 1996).



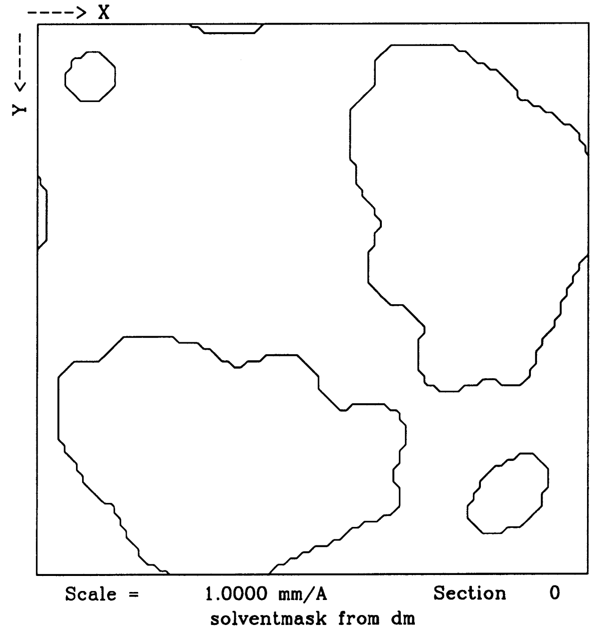


Figure 15.1.2.2
Solvent mask determined from a map by Wang’s method.

15.1.2.1.3. *The solvent-flattening procedure*

Once the envelope has been determined, solvent flattening is performed by simply setting the density in the solvent region to the expected value, $\rho_{\rm solv}$:

$$\rho_{\rm mod}(\mathbf{x}) = \begin{cases} \rho(\mathbf{x}), & \rho_{\rm ave}(\mathbf{x}) > \rho_{\rm cut} \\ \rho_{\rm solv}, & \rho_{\rm ave}(\mathbf{x}) < \rho_{\rm cut} \end{cases}. \qquad (15.1.2.6)$$

If the electron density has not been calculated on an absolute scale, the solvent density may be set to its mean value.

A related method is solvent flipping, developed by Abrahams & Leslie (1996). In this approach, the flattening operation is modified by the introduction of a relaxation factor, γ, where γ is positive, effectively 'flipping' the density in the solvent region.

$$\rho_{\rm mod}(\mathbf{x}) = \begin{cases} \rho(\mathbf{x}), & \rho_{\rm ave}(\mathbf{x}) > \rho_{\rm cut} \\ \rho_{\rm solv} - [\gamma/(1-\gamma)][\rho(\mathbf{x}) - \rho_{\rm solv}], & \rho_{\rm ave}(\mathbf{x}) < \rho_{\rm cut} \end{cases}. \qquad (15.1.2.7)$$

The effect of this modification is to correct for the problem of independence in phase combination and is discussed in Section 15.1.4.3.

15.1.2.2. *Histogram matching*

Histogram matching seeks to bring the distribution of electron-density values of a map to that of an ideal map. The density histogram of a map is the probability distribution of electron-density values. It provides a global description of the appearance of the map, and all spatial information is discarded. The comparison of the histogram for a given map with that expected for an ideal map can serve as a measure of quality. Furthermore, the initial map can be improved by adjusting density values in a systematic way to make its histogram match the ideal histogram.

15.1.2.2.1. *Introduction*

Histogram matching is a standard technique in image processing. It is aimed at bringing the density distribution of an image to an ideal distribution, thereby improving the image quality. The first attempt at modifying the electron-density distribution was that by Hoppe & Gassman (1968), who proposed the '3–2' rule. The electron density was first normalized to a maximum of 1 and modified by imposing positivity. Subsequently, the electron density was modified by $\rho_{\rm mod} = 3\rho^2 - 2\rho^3$. Podjarny & Yonath (1977) used the skewness of the density histogram as a measure of quality of the modified map. Harrison (1988) used a Gaussian function as the ideal histogram in his histogram-specification method for protein phase refinement and extension. The choice of the Gaussian function as the ideal electron-density distribution was based on theoretical arguments instead of experimental evaluation. The Gaussian function was also made independent of resolution. Lunin (1988) used the electron-density distribution to retrieve the values of low-angle structure factors whose amplitudes had not been measured during an X-ray experiment. The electron-density distribution was thought to be structure specific and was derived from a homologous structure. Moreover, the histogram was derived from the entire unit cell, including both the protein and the solvent. Zhang & Main (1988) systematically examined the electron-density histogram of several proteins and found that the ideal density histogram is dependent on resolution, the overall temperature factor and the phase error. It is, however, independent of structural conformation. The sensitivity to phase error suggests that the density histogram could be used for phase improvement. The structural conformation independence made it possible to predict the ideal histogram for unknown structures.

15.1.2.2.2. *The prediction of the ideal histogram*

Polypeptide structures in particular, and biological macromolecules in general, display a broadly similar atomic composition, and the way in which these atoms bond together is also conserved across a wide range of structures. These similarities between different protein structures can be used to predict the ideal histogram even when positional information for individual atoms is not available in a map. If the positional information is removed from an electron-density map, then what remains is an unlabelled list of density values. This list is the histogram of the electron-density distribution, which is independent of the relative disposition of these densities. The shape of the histogram is primarily based on the presence of atoms and their characteristic distances from each other. This is true for all polypeptide structures.

The frequency distribution, $P(\rho)$, of electron-density values in a map can be constructed by sampling the map and counting the density values in different ranges. In practice, once the electron-density map has been sampled on a discrete grid, this frequency distribution becomes a histogram, but for convenience, it is treated here as a continuous distribution.

At resolutions of better than 6.0 Å and after exclusion of the solvent region, the frequency distribution of electron-density values for protein density over a wide range of proteins varies only with resolution and overall temperature factor to a good approximation. If the overall temperature factor is artificially adjusted, for example, by sharpening to $B_{\rm overall} = 0$, then the frequency distributions may be treated as a function of resolution only. Therefore, once a good approximation to the molecular envelope is known, the frequency distribution of electron densities in the protein region as a function of resolution may be assumed to be known. Therefore, the ideal density histogram for an unknown map at a given resolution can be taken from any known structure at the same resolution (Zhang & Main, 1988, 1990*a*).

The ideal electron-density histogram can also be predicted by an analytical formula (Lunin & Skovoroda, 1991; Main, 1990*a*). The method adopted by Main (1990*a*) represents the density histogram by components that correspond to three types of electron density in the map. The first component is the region of overlapping densities, which can be represented by a randomly distributed background noise. The second component is the region of partially overlapping densities. The third component is the region of non-overlapping atomic peaks, which can be represented by a Gaussian.

The histogram for the overlapping part of the density can be represented by a Gaussian distribution,

$$P_o(\rho) = N \exp\bigl[-(\rho - \overline{\rho})^2/2\sigma^2\bigr], \qquad (15.1.2.8)$$

where $\overline{\rho}$ is the mean density and σ is the standard deviation. The region of partially overlapping densities can be modelled by a cubic polynomial function,

$$P_{po}(\rho) = N\bigl(a\rho^3 + b\rho^2 + c\rho + d\bigr). \qquad (15.1.2.9)$$

The histogram for the non-overlapping part of the density can be derived analytically from a Gaussian atom,

$$P_{no}(\rho) = N(A/\rho)[\ln(\rho_0/\rho)]^{1/2}, \qquad (15.1.2.10)$$

where ρ_0 is the maximum density, N is a normalizing factor and A

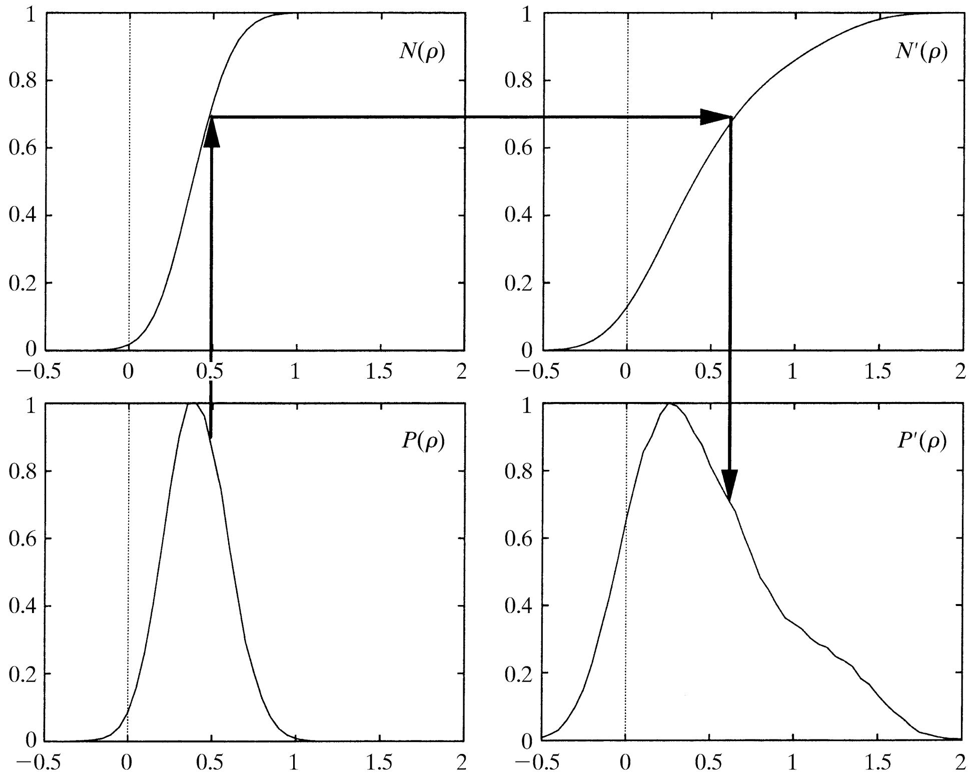

Figure 15.1.2.3
Transformation of density ρ to $\rho'_{\rm mod}$ by histogram matching.

is the relative weight of the terms between equation (15.1.2.8) and equation (15.1.2.10).

If we use two threshold values, ρ_1 and ρ_2, to divide the three density regions, the complete formula can be expressed as

$$P(\rho) = \begin{cases} N \exp\left[-(\rho - \overline{\rho})^2/2\sigma^2\right] & \text{for} \quad 2\rho \le \rho_2 \\ N(a\rho^3 + b\rho^2 + c\rho + d) & \text{for} \quad 2\rho_2 < \rho \le \rho_1 \\ N(A/\rho)[\ln(\rho_0/\rho)]^{1/2} & \text{for} \quad 2\rho_1 < \rho \le \rho_0. \end{cases} \tag{15.1.2.11}$$

The parameters a, b, c, d in the cubic polynomial are calculated by matching function values and gradients at ρ_1 and ρ_2. The parameters in the histogram formula, $\overline{\rho}$, σ, A, ρ_0, ρ_1, ρ_2, can be obtained from histograms of known structures.

15.1.2.2.3. The process of histogram matching

Zhang & Main (1990*a*) demonstrated that, at better than 4 Å resolution, the histogram for an MIR map is generally significantly different from the ideal distribution calculated from atomic coordinates. The obvious course is therefore to alter the map in such a way as to make its density histogram equal to the ideal distribution. Unfortunately, there are an infinite number of maps corresponding to any chosen density distribution, so we must choose a systematic method of altering the map.

The conventional method of performing such a modification is to retain the ordering of the density values in the map. The highest point in the original map will be the highest point in the modified map, the second highest points will correspond in the same way, and so on.

Mathematically, this transformation is represented as follows. Let $P(\rho)$ be the current density histogram and $P'(\rho)$ be the desired distribution, normalized such that their sums are equal to 1. The cumulative distribution functions, $N(\rho)$ and $N'(\rho)$, may then be calculated:

$$\begin{aligned} N(\rho) &= \int_{\rho_{\min}}^{\rho} P(\rho)\, {\rm d}\rho, \\ N'(\rho') &= \int_{\rho_{\min}}^{\rho'} P'(\rho)\, {\rm d}\rho. \end{aligned} \tag{15.1.2.12}$$

The cumulative distribution function of a variable transforms a value chosen from the distribution into a number between 0 and 1, representing the position of that value in an ordered list of values chosen from the distribution.

The transformation may, therefore, be performed in two stages. A density value is taken from the initial distribution and the cumulative distribution function of the initial distribution is applied to obtain the position of that value in the distribution. The inverse of the cumulative distribution function for the desired distribution is applied to this value to obtain the density value for the corresponding point in the desired distribution. Thus, given a density value, ρ, from the initial distribution, the modified value, ρ', is obtained by

$$\rho' = N'^{-1}[N(\rho)]. \tag{15.1.2.13}$$

The distribution of ρ' will then match the desired distribution after the above transformation. The transformation of an electron-density value by this method is illustrated in Fig. 15.1.2.3. The transformation in equation (15.1.2.13) can be achieved through a linear transform represented by

$$\rho'_i = a_i \rho_i + b_i, \tag{15.1.2.14}$$

where $i = \{1, \ldots, n\}$ and n is the number of density bins. The above linear transform is sufficient if the number of density bins is large enough. An n value of about 200 is usually quite satisfactory.

Various properties of the electron density are specified in the density histogram, such as the minimum, maximum and mean density, the density variance, and the entropy of the map. The mean density of the ideal map can be obtained by

$$\overline{\rho} = \int_{\rho_{\min}}^{\rho_{\max}} \rho P(\rho)\,\mathrm{d}\rho. \qquad (15.1.2.15)$$

The variance of the density in the ideal map can be obtained by

$$\sigma(\rho) = \left(\overline{\rho^2} - \overline{\rho}^2\right)^{1/2}, \qquad (15.1.2.16)$$

where

$$\overline{\rho^2} = \int_{\rho_{\min}}^{\rho_{\max}} \rho^2 P(\rho)\,\mathrm{d}\rho. \qquad (15.1.2.17)$$

Therefore, the process of histogram matching applies a minimum and a maximum value to the electron density, imposes the correct mean and variance, and defines the entropy of the new map. The order of electron-density values remains unchanged after histogram matching.

Histogram matching is complementary to solvent flattening since it is applied to the protein region of a map, whereas solvent flattening only operates on the solvent region of the map. The same envelope that was used for isolating the solvent region can be used to determine the protein region of the cell. An alternative approach is to define separate solvent and protein masks, with uncertain regions excluded from either mask and allowed to keep their unmodified values.

15.1.2.2.4. Scaling the observed structure-factor amplitudes according to the ideal density histogram

In the process of density modification, electron density or structure factors from different sources are compared and combined. It is, therefore, crucial to ensure that all the structure factors and maps are on the same scale. The observed structure factors can be put on the absolute scale by Wilson statistics (Wilson, 1949) using a scale and an overall temperature factor. This is accurate when atomic or near atomic resolution data are available. The scale and overall temperature factor obtained from Wilson statistics are less accurate when only medium- to low-resolution data are available. A more robust method of scaling non-atomic resolution data is through the density histogram (Cowtan & Main, 1993; Zhang, 1993).

The ideal density histogram defines the mean and variance of an electron density, as shown in equations (15.1.2.15) and (15.1.2.16). We can scale the observed structure-factor amplitudes to be consistent with the target histogram using the following formula, obtained from the structure-factor equation and Parseval's theorem. The mean density and the density variance of the observed map can be calculated as

$$\overline{\rho}' = (1/V)F(000), \qquad (15.1.2.18)$$

$$\sigma'(\rho) = (1/V)\left[\sum_{\mathbf{h}} |F(\mathbf{h})|^2\right]^{1/2}. \qquad (15.1.2.19)$$

The mean and variance of the electron-density map at the desired resolution are calculated using the target histogram, the mean value of the solvent density, $\overline{\rho}_{\rm solv}$, and the solvent volume of the cell, $V_{\rm solv}$. The $F(000)$ term can then be evaluated from equations (15.1.2.15) and (15.1.2.18):

$$F(000) = (V - V_{\rm solv})\overline{\rho} + V_{\rm solv}\overline{\rho}_{\rm solv}. \qquad (15.1.2.20)$$

The scale of the observed amplitudes can be obtained from equations (15.1.2.16) and (15.1.2.19),

$$F'(\mathbf{h}) = KF(\mathbf{h}), \qquad (15.1.2.21)$$

where

$$K = \left[(\overline{\rho^2} - \overline{\rho}^2)\right]^{1/2} \Big/ \left\{(1/V)\left[\sum_{\mathbf{h}} |F(\mathbf{h})|^2\right]^{1/2}\right\}. \qquad (15.1.2.22)$$

This method is adequate for scaling observed structure factors at any resolution.

15.1.2.3. Averaging

The averaging method enforces the equivalence of electron-density values between grid points in the map related by noncrystallographic symmetry. The averaging procedure can filter noise, correct systematic error and even determine the phases *ab initio* in favourable cases (Chapman *et al.*, 1992; Tsao *et al.*, 1992).

15.1.2.3.1. Introduction

Noncrystallographic symmetry (NCS) arises in crystals when there are two or more of the same molecules in one asymmetric unit. Such symmetries are local, since they only apply within a sub-region of a single unit cell. A fivefold axis, for example, must be noncrystallographic, since it is not possible to tessellate objects with fivefold symmetry. Since the symmetry does not map the crystal lattice back onto itself, the individual molecules that are related by the noncrystallographic symmetry will be in different environments; therefore, the symmetry relationships are only approximate.

Noncrystallographic symmetries provide phase information by the following means. Firstly, the related regions of the map may be averaged together, increasing the ratio of signal to noise in the map. Secondly, since the asymmetric unit must be proportionally larger to hold multiple copies of the molecule, the number of independent diffraction amplitudes available at any resolution is also proportionally larger. This redundancy in sampling the molecular transform leads to additional phase information which can be used for phase improvement.

15.1.2.3.2. The determination of noncrystallographic symmetry

The self-rotation symmetry is now routinely solved by the use of a Patterson rotation function (Rossmann & Blow, 1962). The translation symmetry can be determined by a translation function (Crowther & Blow, 1967) when a search model, either an approximate structure of the protein to be determined or the structure of a homologous protein, is available. The searches of the Patterson rotation and translation functions are achieved typically using fast automatic methods, such as *X-PLOR* (Brünger *et al.*, 1987) or *AMoRe* (Navaza, 1994). In cases where no search model is available or the Patterson translation function is unsolvable, either the whole electron-density map, or a region which is expected to contain a molecule, may be rotated using the rotation solution and used as a search model in a phased translation function (Read & Schierbeek, 1988).

Once the averaging operators are determined, the mask can be determined using the local density correlation function as developed by Vellieux *et al.* (1995). This is achieved by a systematic search for extended peaks in the local density correlation, which must be carried out over a volume of several unit cells in order to guarantee finding the whole molecule. The local correlation function distinguishes those volumes of crystal space which map onto similar density under transformation by the averaging operator. Thus, in the case of improper NCS, a local correlation mask will cover only one monomer. In the case of a proper symmetry, a local correlation mask will cover the whole complex (Fig. 15.1.2.4*a*,*b*).

Special cases arise when there are combinations of crystallographic and noncrystallographic symmetries, of proper and improper symmetries, or when a noncrystallographic symmetry element maps a cell edge onto itself. In the latter case, the volume of matching density is infinite, and arbitrary limits must be placed upon the mask along one crystal axis.

15.1.2.3.3. The refinement of noncrystallographic symmetry

The initial NCS operation obtained from rotation and translation functions or heavy-atom positions can be fine-tuned by a density-space *R*-factor search in the six-dimensional rotation and translation space. The density-space *R* factor is defined as

$$R = \sum_{\mathbf{r}} |\rho(\mathbf{r}) - \rho(\mathbf{r}')| \Big/ \sum_{\mathbf{r}} |\rho(\mathbf{r}) + \rho(\mathbf{r}')|, \qquad (15.1.2.23)$$

where $\mathbf{r} = \{xyz\}$ is the set of Cartesian coordinates, $\mathbf{r}' = \Omega\mathbf{r}$ is the NCS-related set of coordinates of $\mathbf{r}$ and Ω represents the NCS operator.

The six-dimensional search is very time consuming. The search rate can be increased by using only a representative subset of grid points. The NCS operation is systematically altered to find the lowest density-space *R* factor for the selected subset of grid points.

The solution of the NCS operation from the six-dimensional search can be further refined by the following least-squares procedure. If $\rho(\mathbf{r})$ is related to $\rho(\mathbf{r}')$ by the NCS operation, Ω,

$$\rho(\mathbf{r}') = \rho(\Omega\mathbf{r}). \qquad (15.1.2.24)$$

Here, Ω is a function of ω, $\Omega = f(\omega)$, where $\omega = \{\alpha, \beta, \gamma, t_x, t_y, t_z\}$ represents the rotation and translation components of the NCS operation. The solution to the NCS parameters, ω, can be obtained by minimizing the density residual between the NCS-related molecules,

$$\varepsilon(\mathbf{r}) = \rho(\mathbf{r}) - \rho(\Omega\mathbf{r}), \qquad (15.1.2.25)$$

using a least-squares formula of the form

$$\left(\frac{\partial\rho}{\partial\omega}\right)^T \left(\frac{\partial\rho}{\partial\omega}\right) \Delta\omega = \left(\frac{\partial\rho}{\partial\omega}\right)^T \varepsilon(\mathbf{r}), \qquad (15.1.2.26)$$

where $\Delta\omega$ is the shift to the NCS parameters. Here,

$$\frac{\partial\rho}{\partial\omega} = \frac{\partial\rho}{\partial\mathbf{r}}\frac{\partial\mathbf{r}}{\partial\omega}. \qquad (15.1.2.27)$$

The partial derivatives, $\partial\rho/\partial\mathbf{r} = \{\partial\rho/\partial x,\ \partial\rho/\partial y,\ \partial\rho/\partial z\}$, can be calculated by Fourier transforms,

$$\begin{aligned}
\frac{\partial\rho}{\partial x} &= -\frac{2\pi i}{V}\sum_{hkl} hF_{hkl}\exp[-2\pi i(hx + ky + lz)] \\
\frac{\partial\rho}{\partial y} &= -\frac{2\pi i}{V}\sum_{hkl} kF_{hkl}\exp[-2\pi i(hx + ky + lz)] \qquad (5.1.2.28) \\
\frac{\partial\rho}{\partial z} &= -\frac{2\pi i}{V}\sum_{hkl} lF_{hkl}\exp[-2\pi i(hx + ky + lz)],
\end{aligned}$$

or more efficiently with a single Fourier transform by the use of spectral B-splines (Cowtan & Main, 1998). $\partial\mathbf{r}/\partial\omega$ is derived analytically based on the relationship between the Cartesian coordinates, *r*, and the rotational and translational coordinates of the NCS operation, ω,

$$\begin{pmatrix} x' \\ y' \\ z' \end{pmatrix} = \begin{pmatrix} \cos\alpha\cos\beta\cos\gamma - \sin\alpha\sin\gamma & -\cos\alpha\cos\beta\sin\gamma - \sin\alpha\sin\gamma & \cos\alpha\sin\beta \\ \sin\alpha\cos\beta\cos\gamma + \cos\alpha\sin\gamma & -\sin\alpha\cos\beta\sin\gamma + \cos\alpha\cos\gamma & \sin\alpha\sin\beta \\ -\sin\beta\cos\gamma & \sin\beta\sin\gamma & \cos\beta \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} t_x \\ t_y \\ t_z \end{pmatrix}. \qquad (15.1.2.29)$$

Types of noncrystallographic symmetry and averaging calculation.

15.1.2.3.4. The averaging of NCS-related molecules

Once the mask and matrices are determined, the electron-density map may be modified by averaging. This can be achieved in one or two stages: The density for each copy of the molecule in the asymmetric unit may be replaced by the averaged density from every copy; however, this becomes slow for high-order NCS (Fig. 15.1.2.4*c*). Alternatively, a single averaged copy of the molecule may be created in an artificial cell [referred to by Rossmann *et al.* (1992) as an *H*-cell], and then each copy of the molecule may be reconstructed in the asymmetric unit from this copy (Fig. 15.1.2.4*d*). This is more efficient for high-order NCS, but additional errors are introduced in the second interpolation.

Interpolation of electron-density values at non-map grid sites is usually required, since the NCS operators will not normally map grid points onto each other. To obtain accurate interpolated values, either a fine grid or a complex interpolation function are required; suitable functions are described in Bricogne (1974) and Cowtan & Main (1998). Solvent flattening and histogram matching are frequently applied after averaging, since histogram matching tends to correct for any smoothing introduced by density interpolation.

In the case of flexible proteins, it may be necessary to average only part of the molecule, in which case the averaging mask will exclude some parts of the unit cell which are indicated as protein by the solvent mask. In other cases, it may be necessary to apply multi-domain averaging; in this case, the protein is divided into rigid domains which can appear in differing orientations. Each domain must then have a separate mask and set of averaging matrices.

Averaging may also be performed across similar molecules in multiple crystal forms (Schuller, 1996); in this case, density modification is performed on each crystal form simultaneously, with averaging of the molecular density across all copies of the molecule in all crystal forms. This is a powerful technique for phase improvement, even when no phasing is available in some crystal forms.

15.1.2.4. Skeletonization

The skeletonization method enhances connectivity in the map. This is achieved by locating ridges of density, constructing a graph of linked peaks, and then building a new map using cylinders of density around the graph peaks.

At worse than atomic resolution, the density peaks for bonded atoms are no longer resolved, and so interpretation of the density in terms of atomic positions involves recognition of common motifs in the pattern of ridges in the density. Skeletonization was a tool developed by Greer (1985) to assist model building by tracing high ridges in the electron density to describe the connectivity in the map.

Skeletonization has more recently been adapted to the problem of density modification (Baker, Bystroff *et al.*, 1993; Bystroff *et al.*, 1993; Wilson & Agard, 1993). A skeleton is constructed by tracing the ridges in the map. The resulting ridges form connected 'trees'. These trees may be pruned to remove small unconnected fragments and break circuits to select for protein-like features. A new map may then be built by building density around the links of the skeleton using the profile of a cylindrically averaged atom at the appropriate resolution.

The skeletonization method has been used to add new features to a partial model of a molecule (Baker, Bystroff *et al.*, 1993). An efficient alternative algorithm for tracing density ridges is given by Swanson (1994).

15.1.2.5. Sayre's equation

Sayre's equation constrains the local shape of electron density. It provides a link between all structure-factor amplitudes and phases. It is an exact equation at atomic resolution in an equal-atom system. It is, therefore, very powerful for phase refinement and extension for small molecules at atomic resolution (Sayre, 1952, 1972, 1974). However, its power diminishes as resolution decreases. It can still be an effective tool for macromolecular phase refinement and extension if the shape function can be modified to accommodate the overlap of atoms at non-atomic resolution (Zhang & Main, 1990*b*).

15.1.2.5.1. Sayre's equation in real and reciprocal space

Sayre's equation (Sayre, 1952, 1972, 1974) expresses the constraint on structure factors when the atoms in a structure are equal and resolved, and the equation has formed the foundation of direct methods. In protein calculations, the resolution is generally too poor for atoms to be resolved, and this is reflected in the bulk of the terms required to calculate the equation for any particular missing structure factor.

For equal and resolved atoms, squaring the electron density changes only the shape of the atomic peaks and not their positions. The original density may therefore be restored by convoluting with some smoothing function, $\psi(\mathbf{x})$, which is a function of atomic shape,

$$\rho(\mathbf{x}) = (V/N)\sum_{\mathbf{y}}\rho^2(\mathbf{y})\psi(\mathbf{x}-\mathbf{y}), \qquad (15.1.2.30)$$

where

$$\psi(\mathbf{x}-\mathbf{y}) = (1/V)\sum_{\mathbf{h}}\theta(\mathbf{h})\exp[2\pi i\mathbf{h}\cdot(\mathbf{x}-\mathbf{y})]. \qquad (15.1.2.31)$$

Here, $\theta(\mathbf{h})$ is the ratio of scattering factors of real, $f(\mathbf{h})$, and 'squared', $g(\mathbf{h})$, atoms, and V is the unit-cell volume, *i.e.*,

$$\theta(\mathbf{h}) = f(\mathbf{h})/g(\mathbf{h}). \qquad (15.1.2.32)$$

Sayre's equation states that the convolution of the squared electron density with a shape function restores the original electron density. It can be seen from equation (15.1.2.30) that Sayre's equation puts constraints on the local shape of electron density. The local shape function is the Fourier transform of the ratio of scattering factors of the real and 'squared' atoms.

Sayre's equation is more frequently expressed in reciprocal space as a system of equations relating structure factors in amplitude and phase:

$$F(\mathbf{h}) = [\theta(\mathbf{h})/V]\sum_{\mathbf{k}}F(\mathbf{k})F(\mathbf{h}-\mathbf{k}). \qquad (15.1.2.33)$$

The reciprocal-space expression of Sayre's equation can be obtained directly from a Fourier transformation of both sides of equation (15.1.2.30) and the application of the convolution theorem.

15.1.2.5.2. The application of Sayre's equation to macromolecules at non-atomic resolution – the θ(h) curve

Sayre's equation is exact for an equal-atom structure at atomic resolution. The reciprocal-space shape function, $\theta(\mathbf{h})$, can be calculated analytically from the ratio of the scattering factors of real and 'squared' atoms, which can both be represented by a Gaussian function. At infinite resolution, we expect $\theta(\mathbf{h})$ to be a spherically symmetric function that decreases smoothly with increased **h**. However, for data at non-atomic resolution, the $\theta(\mathbf{h})$ curve will behave differently because atomic overlap changes the peak shapes. Therefore, a spherical-averaging method is adopted to obtain an estimate of the shape function empirically from the ratio of the observed structure factors and the structure factors from the squared electron density using the formula

$$\theta(s) = V\left\langle F(\mathbf{h})\Big/\sum_{\mathbf{k}}F(\mathbf{k})F(\mathbf{h}-\mathbf{k})\right\rangle_{|\mathbf{h}|}, \qquad (15.1.2.34)$$

where the averaging is carried out over ranges of $|\mathbf{h}|$, *i.e.*, over spherical shells, each covering a narrow resolution range. Here, s represents the modulus of **h**.

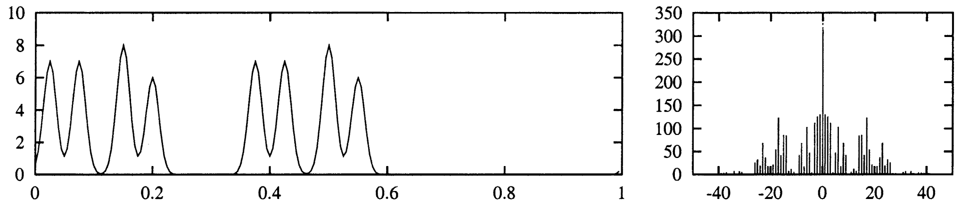
The empirically derived shape function only extends to the resolution of the experimentally observed phases. This is sufficient for phase refinement. However, there are no experimentally observed phases to give the empirical $\theta(s)$ for phase extension. Therefore, a Gaussian function of the form

$$\theta(s) = K\exp(-Bs^2) \qquad (15.1.2.35)$$

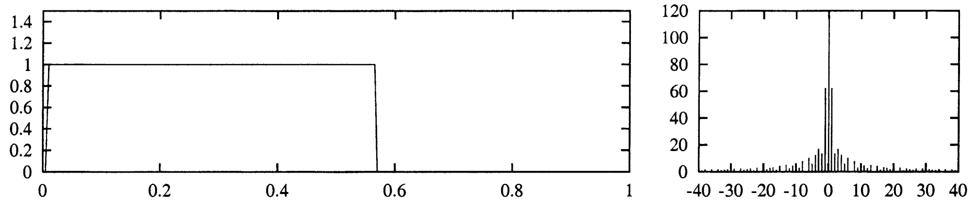
is fitted to the available values of $\theta(s)$, and the parameters K and B are obtained using a least-squares method. The shape function $\theta(s)$ for the resolution beyond that of the observed phases is extrapolated using the fitted Gaussian function. The derivation of the shape function $\theta(s)$ from a combination of spherical averaging and Gaussian extrapolation is the key to the successful application of Sayre's equation for phase improvement at non-atomic resolution (Zhang & Main, 1990*b*).

15.1.2.6. Atomization

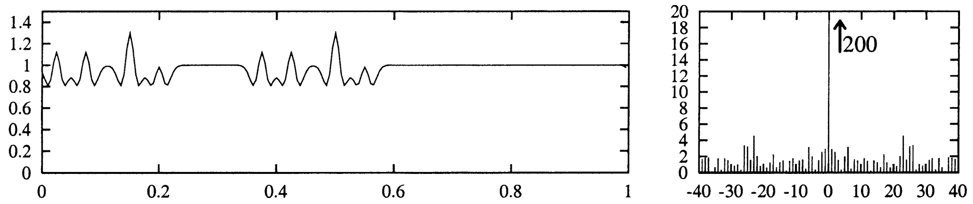
The atomization method uses the fact that the structure underlying the map consists of discrete atoms. It attempts to



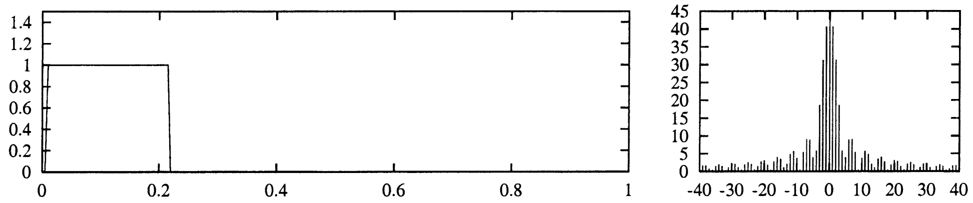
Electron density and structure-factor magnitudes



Solvent-flattening function $g_{\mathrm{sf}}(\mathbf{x})$ and $G_{\mathrm{sf}}(\mathbf{h})$



Histogram-matching function $g_{\mathrm{hm}}(\mathbf{x})$ and $G_{\mathrm{hm}}(\mathbf{h})$



Averaging function $g_{\mathrm{ave}}(\mathbf{x})$ and $G_{\mathrm{ave}}(\mathbf{h})$

Figure 15.1.3.1
The functions $g(\mathbf{x})$ and $G(\mathbf{h})$ for solvent flattening, histogram matching and averaging.

interpret the map by automatically placing atoms and refining their positions.

Agarwal & Isaacs (1977) proposed a method for the extension of phases to higher resolutions by interpreting an electron-density map in terms of 'dummy' atoms. These are so called because at the initial resolution of 3.0 Å, true atom peaks could not be resolved. The placement of 'dummy atoms' is subject to constraints of bonding distance and the number of neighbours. The coordinates and temperature factors of these dummy atoms may then be refined against all the available diffraction amplitudes. Structure factors may then be calculated from the refined coordinates to provide phases for the high-resolution reflections and to improve the phases of the starting set.

The atomization approach has been extended in the *ARP* program (Lamzin & Wilson, 1997) by the use of difference-map criteria to test dummy-atom assignments, with the aim of removing wrong atoms and introducing missing atoms. With modern refinement algorithms, this technique has become very effective for the solution of structures at high resolution from a poor molecular-replacement model, or even directly from an MIR/MAD map.

Map improvement has also been demonstrated at intermediate resolutions by Perrakis *et al.* (1997) using a multi-solution variant of the *ARP* method, and by Vellieux (1998).

The interpretation of an approximately phased map has also been applied very successfully as part of the 'Shake n' Bake' direct-methods procedure (Miller *et al.*, 1993; Weeks *et al.*, 1993). The alternating application of phase refinement by the minimum principle in reciprocal space ('Shake') and atomization in real space ('Bake') has proved to be a very powerful method for solving small protein structures at atomic resolution using only structure-factor amplitudes.

15.1.3. Reciprocal-space interpretation of density modification

Density modification, although mostly performed in real space for ease of application, can be understood in terms of reciprocal-space constraints on structure-factor amplitudes and phases.

Main & Rossmann (1966) showed that the NCS-averaging operation in real space can be expressed in reciprocal space as the convolution of the structure factors and the Fourier transform of the molecular envelope and the NCS matrices. Similarly, the solvent-flattening operation can be considered a multiplication of the map by some mask, $g_{\mathrm{sf}}(\mathbf{x})$, where $g_{\mathrm{sf}}(\mathbf{x}) = 1$ in the protein region and $g_{\mathrm{sf}}(\mathbf{x}) = 0$ in the solvent region. Thus

$$\rho_{\mathrm{mod}}(\mathbf{x}) = g_{\mathrm{sf}}(\mathbf{x}) \times \rho(\mathbf{x}). \qquad (15.1.3.1)$$

This assumes that the solvent level is zero, which can be achieved by suitable adjustment of the $F(000)$ term.

If we transform this equation to reciprocal space, then the product becomes a convolution; thus

$$F_{\mathrm{mod}}(\mathbf{h}) = (1/V)\sum_{\mathbf{k}} G_{\mathrm{sf}}(\mathbf{k})F(\mathbf{h} - \mathbf{k}), \qquad (15.1.3.2)$$

where $G_{\rm sf}(\mathbf{k})$ is the Fourier transform of the mask $g_{\rm sf}(\mathbf{x})$. The solvent mask $g_{\rm sf}(\mathbf{x})$ shows the outline of the molecule with no internal detail, so must be a low-resolution image. Therefore, all but the lowest-resolution terms of $G_{\rm sf}$ will be negligible.

The convolution expresses the relationship between phases in reciprocal space from the constraint of solvent flatness in real space. Since only the terms near the origin of $G_{\rm sf}$ are nonzero, the convolution can only relate phases that are local to each other in reciprocal space. Thus, it can only provide phase information for structure factors near the current phasing resolution limit.

This reasoning may also be applied to other density modifications. Histogram matching applies a nonlinear rescaling to the current density in the protein region. The equivalent multiplier, $g_{\rm hm}(\mathbf{x})$, shows variations of about 1.0 that are related to the features in the initial map. The function $G_{\rm hm}(\mathbf{h})$ for histogram matching is, therefore, dominated by its origin term, but shows significant features to the same resolution as the current map or further, as the density rescaling becomes more nonlinear. Histogram matching can therefore give phase indications to twice the resolution of the initial map or beyond, although phase indications will be weak and contain errors related to the level of error in the initial map.

$$\rho_{\rm mod}(\mathbf{x}) = g_{\rm ncs}(\mathbf{x})(1/N_{\rm ncs})\sum_i \rho_i(\mathbf{x}). \tag{15.1.3.3}$$

Averaging may be described as the summation of a number of reoriented copies of the electron density within the region of the averaging mask (Main & Rossmann, 1966), *i.e.* where $\rho_i(\mathbf{x})$ is the initial density, $\rho(\mathbf{x})$, transformed by the ith NCS operator and $g_{\rm ncs}(\mathbf{x})$ is the mask of the molecule to be averaged. This summation is repeated for each copy of the molecule in the whole unit cell. The reciprocal-space averaging function, $G_{\rm ncs}(\mathbf{h})$, is the Fourier transform of a mask, as for solvent flattening, but since the mask covers only a single molecule, rather than the molecular density in the whole unit cell, the extent of $G_{\rm ncs}(\mathbf{h})$ in reciprocal space is greater.

Sayre's equation is already expressed as a convolution, although in this case the function $G(\mathbf{h})$ is given by the structure factors $F(\mathbf{h})$ themselves. It is, therefore, the most powerful method for phase extension. However, as resolution decreases, more of the reflections required to form the convolution are missing, and the error increases.

The functions $g(\mathbf{x})$ and $G(\mathbf{h})$ for these density modifications are illustrated in Fig. 15.1.3.1 for a simple one-dimensional structure.

15.1.4. Phase combination

Phase combination is used to filter the noise in the modified phases and eliminate the incorrect component of the modified phases through a statistical process. The observed structure-factor amplitudes are used to estimate the reliability of the phases after density modification. The estimated probability of the modified phases is combined with the probability of observed phases to produce a more reliable phase estimate,

$$P_{\rm new}[\varphi(\mathbf{h})] = P_{\rm obs}[\varphi(\mathbf{h})]P_{\rm mod}[\varphi(\mathbf{h})]. \tag{15.1.4.1}$$

Once a modified map has been obtained, modified phases and amplitudes may be derived from an inverse Fourier transform. The modified phases are normally combined with the initial phases by multiplication of their probability distributions. The probability distribution for the experimentally observed phases is usually described in terms of a best phase and figure of merit (Blow & Rossmann, 1961) or by Hendrickson–Lattman coefficients (Hendrickson & Lattman, 1970). In order to estimate a unimodal probability distribution for the modified phase, some estimate of the associated error must be made; this is usually achieved using the Sim weighting scheme (Sim, 1959).

Recombination with the initial phases assumes independence between the initial and modified phases and is a source of difficulties. However, in the absence of some form of phase constraint, most density-modification constraints are too weak to guarantee convergence to a reasonable solution. The exception is when high-order NCS is present; in this case, the combination of NCS and observed amplitudes is sufficient to determine the phases (Chapman *et al.*, 1992; Tsao *et al.*, 1992), and phase combination may be omitted; however, weighting of the phases is still necessary. In this case, it is also possible to restore missing reflections in both amplitude and phase.

15.1.4.1. Sim and σ_a weighting

The phase probability distribution for the density-modified phase is conventionally generated under assumptions that were made for the combination of a partial atomic model with experimental data. It assumes that the calculated amplitudes and phases arise from a density map in which some atoms are present and correctly positioned, and the remainder are completely absent (Sim, 1959). Thus, the difference between the true structure factor and the calculated value must be the effective structure factor due to the missing density alone. If the phase of this quantity is random and the amplitude is drawn from a Wilson distribution (Wilson, 1949), the following expression is obtained:

$$P_{\rm mod}(\varphi) = \exp[A\cos\varphi + B\sin\varphi], \tag{15.1.4.2}$$

where

$$\begin{aligned} A &= X\cos\varphi_{\rm exp} \\ B &= X\sin\varphi_{\rm exp} \end{aligned} \tag{15.1.4.3}$$

and

$$X = 2|F_{\rm exp}||F_{\rm mod}|/\Sigma_Q, \tag{15.1.4.4}$$

where Σ_Q is the variance parameter in the Wilson distribution for the missing part of the structure. The figure of merit, w, can be derived from

$$w = I_1(X)/I_0(X), \tag{15.1.4.5}$$

where I_0 and I_1 are zero- and first-order modified Bessel functions. A similar argument follows for centric reflections.

The error estimate for the phase depends on the effective amount of missing structure that is estimated on the basis of the agreement of the modified amplitudes with their measured values, where Σ_Q may be estimated by a number of means, for example (Bricogne, 1976),

$$\Sigma_Q = \langle |F_{\rm obs}|^2 - |F_{\rm mod}|^2 \rangle, \tag{15.1.4.6}$$

where the average is normally taken over all reflections at a particular resolution. A more sophisticated approach is the σ_a method of Read (1986), which allows for errors in the atomic model and has also been used in density modification (Chapter 15.2).

Although these approaches have been applied with some success, the assumption in equation (15.1.4.1) that the density-modified amplitudes and phases are independent of the initial values is invalid. Since the density constraints are typically underdetermined, it is possible to achieve an arbitrarily good agreement between the model amplitudes and their observed values without improving the phases. As a result, phase weights from density modification are typically overestimated.

This problem has traditionally been addressed by limiting the number of cycles of density modification in which weakly phased reflections are included. Typically, density modification is started with only some subset of the data, such as those reflections well phased from MIR data. Only these reflections are included in the phase recombination, with other reflections set to zero. As the calculation progresses, more reflections are introduced until all the data are included. The figures of merit of reflections that undergo fewer cycles of phase recombination will be correspondingly smaller (*e.g.* Leslie, 1987; Zhang & Main, 1990*a*). In averaging calculations where considerable phase information is available from high-order NCS, it is still typically necessary to perform phase extension over hundreds of cycles and to add a very thin resolution shell of new reflections at each cycle.

The phases and figure of merit generated from density modification are more suited to the calculation of weighted F_o maps than $2mF_o - F_c$ maps. The $2mF_o - F_c$ map is designed to aid the structure completion from a partial model (Main, 1979). The $2mF_o - F_c$ map will restore features missing from the current model at full weight if the following conditions are fulfilled. First, the model phases must be close to their true values. Secondly, the difference between the model and observed amplitudes is a good indicator of the phase error and the difference between the calculated and observed amplitudes decreases as the phases approach their true values. Neither of these assumptions are necessarily true for density modification, since it may be applied to very poor maps with almost random phases, and under most density-modification schemes the structure-factor amplitudes may be over-fitted to the observed values.

15.1.4.2. *Reflection omit*

The modified map may be made more independent of the original map, as was assumed when multiplying the phase probability distributions in equation (15.1.4.1), through a reciprocal-space analogue of the omit map, the reflection-omit method.

The reflections are divided into (typically 10 or 20) sets and density-modification calculations are performed, excluding each set in turn from the calculation of the starting map, in a manner similar to a free-*R*-value calculation (Brünger, 1992). Density modification is applied to each map in turn, and the modified reflections from each of the free sets are combined to give a new, complete data set. This data set should be less dependent on the original amplitudes; therefore, the amplitudes may be expected to give a better indication of the quality of the modified phases.

The resulting maps obtained using solvent flattening and/or histogram matching are dramatically improved using the reflection-omit method (Cowtan & Main, 1996). In the case of averaging calculations, however, the reflection-omit approach makes little difference, since omitted reflections tend to be restored through noncrystallographic symmetry relationships to other regions of reciprocal space. It is possible that further improvements may be achieved by selecting reflection sets that approximately obey the NCS relationships.

15.1.4.3. *The γ correction and solvent flipping*

Abrahams & Leslie (1996) have shown that solvent flipping is dramatically more effective as a density modification than solvent flattening. This may be shown to be theoretically equivalent to performing a reflection-omit calculation for each reflection individually (Abrahams, 1997).

Solvent flattening is represented in reciprocal space by convolution of the structure factors with a function, $G(\mathbf{h})$, as shown in equation (15.1.3.2). If the origin term of G is set to zero, then the modified structure factor, $F_{\rm mod}(\mathbf{h})$, will depend on the values of all the structure factors except itself; this is equivalent to performing a reflection-omit calculation with that reflection alone omitted.

Let the origin-removed G be called $G_\gamma(\mathbf{h})$ and its Fourier transform $g_\gamma(\mathbf{x})$:

$$G_\gamma(\mathbf{h}) = \begin{cases} 0, & \mathbf{h} = 0 \\ G(\mathbf{h}), & \mathbf{h} \neq 0 \end{cases}, \qquad (15.1.4.7)$$

then

$$g_\gamma(\mathbf{x}) = g(\mathbf{x}) - \overline{g(\mathbf{x})}. \qquad (15.1.4.8)$$

The convolution of the reflection data with $G_\gamma(\mathbf{h})$ is equivalent to performing a reflection-omit calculation, omitting every reflection in turn. However, the convolution may still be performed in real space; thus, the full omit calculation becomes a simple multiplication of the map by $g_\gamma(\mathbf{x})$:

$$\rho_{\rm mod}(\mathbf{x}) = g_\gamma(\mathbf{x}) \times \rho(\mathbf{x}). \qquad (15.1.4.9)$$

In a solvent-flattening calculation, $g_\gamma(\mathbf{x})$ will be equal to $g(\mathbf{x})$ minus the fraction of the cell that is protein. In the case of a cell with 50% solvent, $g_\gamma(\mathbf{x})$ has a value of 0.5 in the protein and -0.5 in the solvent. Multiplication of the map by this function results in flipping of the solvent.

If the origin term of the G function, γ, can be determined, then the flipping calculation may alternatively be performed by subtracting a copy of the initial map scaled by γ from the modified map. This is the γ correction of Abrahams (1997). This approach may be generalized to arbitrary density-modification methods by use of the perturbation γ (Cowtan, 1999). In this approach, a random perturbation is applied to the starting data. Density modification is applied to both the perturbed and unperturbed maps. The relative size of the perturbation signal in the modified map gives an estimate for γ. The perturbation γ provides effective bias correction for any combination of solvent flattening, histogram matching and averaging. γ may also be estimated as a function of resolution, allowing successful application to multi-resolution modification and possibly atomization as well.

15.1.4.4. *Resolution extrapolation*

The Fourier coefficients of the density-modified map include nonzero contributions for reflections that were not present in the original electron-density map. These values are commonly used to restore the values of reflections that were missing from the original data (including low-resolution reflections falling behind the backstop). However, they have recently also been employed to extrapolate structure factors beyond the resolution of the observed data (Caliandro *et al.*, 2005; Usón *et al.*, 2007).

In the scheme of Usón *et al.*, the Fourier coefficients of the density-modified map are normalized to obey a Wilson distribution (calculated using the overall temperature factor of the observed data). These are then used in the calculation of the next electron-density map. At high resolution (1.35 Å in the case reported), this procedure leads to both improved phases for the observed structure factors at lower resolutions and good estimates for the extrapolated structure factors – these can be judged by comparison with the calculated values obtained from the final refined model. The resulting electron-density map obtained using density modification alone can rival the quality of the final 'best' map obtained from refinement.

The theoretical basis for the effectiveness of this approach has yet to be fully explained. Current implementations are mainly effective at high resolution, where the extrapolated resolution can approach atomic resolution.

15.1.5. Combining constraints for phase improvement

The chemical and physical information of the underlying structure that the electron density represents serves as constraints on the phases. For small molecules, the constraints of positivity and atomicity are sufficient to solve the phase problem *ab initio* (Hauptman, 1986; Karle, 1986; Woolfson, 1987), because crystals of small molecules generally diffract to atomic resolution. However, no single constraint at our disposal is powerful enough to render the macromolecular phase problem determinable, because macromolecule crystals rarely diffract to atomic resolution. Therefore, individual constraints are combined to produce a more powerful density-modification protocol. This is because these constraints represent different characteristic features of the electron density and they contain independent phasing information.

The phasing power of a method increases with the number of independent constraints employed, the number of density points affected and the amplitude of changes imposed on the electron density. It also depends on the physical nature and accuracy of the constraints and how the constraints are applied. One obvious way of implementing several constraints is to apply them one after the other to the electron density. This sequential application, although easy to implement, suffers some drawbacks. The cyclic application of all constraints may not converge easily, since some constraints may contain contradicting information as to how the density should be modified. An alternative way of implementing various constraints is simultaneous application. The density solution that satisfies all the constraints is obtained by a global minimization procedure (Main, 1990*b*; Zhang & Main, 1990*b*).

15.1.5.1. The system of nonlinear constraint equations

The constraints used in *SQUASH/DM* can be divided into three categories. The first category comprises the linear constraints, such as solvent flatness, density histogram and equal molecules. The second category comprises the nonlinear constraints, such as the local shape of electron density as expressed in Sayre's equation. The third category comprises the available structural data, such as the observed structure-factor amplitudes and the experimental phases. The first and second categories of constraints are used to solve new electron-density values. The third category of constraints is used as a means to filter the modified phases.

The modification to the density value at a grid point by a linear constraint is independent of the values at other grid points. These constraints include solvent flattening, histogram matching and molecular averaging. These density-modification methods construct an improved map directly from an initial density map as expressed by

$$\rho(\mathbf{x}) = H(\mathbf{x}), \qquad (15.1.5.1)$$

where $H(\mathbf{x})$ is the target electron density produced by these linear constraints.

The new electron density that satisfies both the linear constraints represented by equation (15.1.5.1) and the nonlinear constraints expressed by Sayre's equation (15.1.2.30) can be obtained by solving the systems of simultaneous equations (Zhang & Main, 1990*b*)

$$\begin{cases} (V/N)\sum_{\mathbf{y}}\rho^2(\mathbf{y})\psi(\mathbf{x}-\mathbf{y}) - \rho(\mathbf{x}) = 0 \\ H(\mathbf{x}) - \rho(\mathbf{x}) = 0 \end{cases}. \qquad (15.1.5.2)$$

Equation (15.1.5.2) represents a system of nonlinear simultaneous equations with as many unknowns as the number of grid points in the asymmetric unit of the map and with twice as many equations as unknowns. The functions $H(\mathbf{x})$ and $\psi(\mathbf{x}-\mathbf{y})$ are both known. The least-squares solution, using either the full matrix or the diagonal approximation, is obtained using the Newton–Raphson technique with fast Fourier transforms, as described in the next section (Main, 1990*b*).

15.1.5.2. Least-squares solution to the system of nonlinear constraint equations

For a system of nonlinear equations of electron density,

$$\mathbf{F}(\rho(\mathbf{x})) = \mathbf{0}, \qquad (15.1.5.3)$$

where

$$\mathbf{F}(\rho(\mathbf{x})) = \left[F_1(\rho(\mathbf{x}))\ F_2(\rho(\mathbf{x}))\ \ldots\ F_m(\rho(\mathbf{x}))\right]^T,$$
$$\rho(\mathbf{x}) = \left[\rho_1\ \rho_2\ \ldots\ \rho_n\right]^T,$$

$\mathbf{0}$ is a null vector, n is the number of grid points and m is the number of equations, the Newton–Raphson method of solution is to find a set of shifts, $\delta\rho(\mathbf{x})$ to $\rho(\mathbf{x})$, through a system of linear equations,

$$\mathbf{J}\delta\rho(\mathbf{x}) = -\varepsilon, \qquad (15.1.5.4)$$

where $\mathbf{J}$ is a matrix of partial derivatives of $\mathbf{F}$ with respect to $\rho(\mathbf{x})$ and is called the Jacobian matrix,

$$\mathbf{J} = \begin{bmatrix} \frac{\partial F_1}{\partial \rho_1} & \frac{\partial F_1}{\partial \rho_2} & \cdots & \frac{\partial F_1}{\partial \rho_n} \\ \frac{\partial F_2}{\partial \rho_1} & \frac{\partial F_2}{\partial \rho_2} & \cdots & \frac{\partial F_2}{\partial \rho_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial F_m}{\partial \rho_1} & \frac{\partial F_m}{\partial \rho_2} & \cdots & \frac{\partial F_m}{\partial \rho_n} \end{bmatrix}, \qquad (15.1.5.5)$$

ε is a vector of residuals to equation (15.1.5.3) for a trial solution, $\rho(\mathbf{x})$, and $\delta\rho(\mathbf{x})$ is a vector of shifts to the density. Hence, the solution for $\rho(\mathbf{x})$ is achieved in an iterative manner,

$$\rho^{i+1}(\mathbf{x}) = \rho^i(\mathbf{x}) + \delta\rho(\mathbf{x}). \qquad (15.1.5.6)$$

Therefore, the problem of solving a system of nonlinear equations (15.1.5.3) is transformed into solving a system of linear equations (15.1.5.4), which forms one cycle of Newton–Raphson iteration.

If there are more equations than unknowns ($m > n$), the unknowns are obtained through a least-squares solution to equations (15.1.5.4),

$$\mathbf{J}^T\mathbf{J}\delta\rho(\mathbf{x}) = -\mathbf{J}^T\varepsilon. \qquad (15.1.5.7)$$

Theoretically, the above system of equations could be solved by matrix multiplication and inversion, *i.e.*

$$\delta\rho(\mathbf{x}) = -\left(\mathbf{J}^T\mathbf{J}\right)^{-1}\mathbf{J}^T\varepsilon. \qquad (15.1.5.8)$$

However, the amount of calculation involved in setting up the normal matrix of least squares is huge for the problem presented by protein structures. This can be completely avoided by using the conjugate-gradient technique for solving the system of linear equations.

15.1.5.2.1. The conjugate-gradient method

The conjugate-gradient method does not require the inversion of the normal matrix, and therefore the solution to a large system of linear equations can be achieved very quickly.

Starting from a trial solution to equations (15.1.5.4), such as a null vector,

$$\delta\rho_0(\mathbf{x}) = \mathbf{0}, \qquad (15.1.5.9)$$

the initial residual is

$$\mathbf{r}_0 = -\mathbf{J}^T(\varepsilon - \mathbf{J}\delta\rho_0(\mathbf{x})) \qquad (15.1.5.10)$$

and the initial search step is

$$\mathbf{p}_0 = \mathbf{r}_0. \qquad (15.1.5.11)$$

The iterative process is as follows. The new shift to the density is

$$\delta\rho_{k+1}(\mathbf{x}) = \delta\rho_k(\mathbf{x}) + \alpha_k\mathbf{p}_k, \qquad (15.1.5.12)$$

where

$$\alpha_k = \mathbf{r}_k^T\mathbf{p}_k/\mathbf{q}_k^T\mathbf{q}_k \qquad (15.1.5.13)$$

and

$$\mathbf{q}_k = \mathbf{J}\mathbf{p}_k. \qquad (15.1.5.14)$$

The new residual is

$$\mathbf{r}_{k+1} = \mathbf{r}_k - \alpha_k\mathbf{s}_k, \qquad (15.1.5.15)$$

where

$$\mathbf{s}_k = \mathbf{J}^T\mathbf{q}_k. \qquad (15.1.5.16)$$

The next search step which conjugates with the residual is

$$\mathbf{p}_{k+1} = \mathbf{r}_{k+1} + \beta_k\mathbf{p}_k, \qquad (15.1.5.17)$$

where

$$\beta_k = -\mathbf{r}_{k+1}^T\mathbf{s}_k/\mathbf{q}_k^T\mathbf{q}_k. \qquad (15.1.5.18)$$

The process is iterated by increasing k until convergence is reached, when

$$\left|\mathbf{r}_{k+1} - \mathbf{r}_k\right| \Rightarrow 0.$$

The number of iterations required for an exact solution is equal to the number of unknowns, because the search vector at each step is orthogonal with all the previous steps. However, a very satisfactory solution can normally be reached after very few iterations. This makes the conjugate-gradient method a very efficient and fast procedure for solving a system of equations. Note that the normal matrix never appears explicitly, although it is implicit in (15.1.5.10) and (15.1.5.16). The inversion of the normal matrix and matrix multiplication is completely avoided. Most of the calculation comes from the formation of the matrix-vector products in (15.1.5.10), (15.1.5.14) and (15.1.5.16). These can be expressed as convolutions and can be performed using FFTs, thus saving considerably more time.

The solution to $\delta\rho(\mathbf{x})$ at the end of conjugate-gradient iteration is substituted into equation (15.1.5.6) to get a new solution for $\rho(\mathbf{x})$. The solution to the system of nonlinear equations (15.1.5.3) is obtained when the Newton–Raphson iteration has reached convergence.

15.1.5.2.2. The full-matrix solution

The equations to be solved for the electron-density shifts, $\delta\rho(\mathbf{x})$, are from the Jacobian of equation (15.1.5.2),

$$\left\{\begin{array}{l}(2V/N)\sum\limits_{\mathbf{y}}\rho(\mathbf{y})\psi(\mathbf{x}-\mathbf{y}) - \delta\rho(\mathbf{x}) = \Delta\rho(\mathbf{x})\\ \delta\rho(\mathbf{x}) = \Delta H(\mathbf{x})\end{array}\right., \qquad (15.1.5.19)$$

where $\Delta\rho(\mathbf{x})$ is the residual to Sayre's equation,

$$\Delta\rho(\mathbf{x}) = \rho(\mathbf{x}) - (V/N)\sum_{\mathbf{y}}\rho^2(\mathbf{y})\psi(\mathbf{x}-\mathbf{y}), \qquad (15.1.5.20)$$

and $\Delta H(\mathbf{x})$ is the residual to the linear density-modification equations,

$$\Delta H(\mathbf{x}) = H(\mathbf{x}) - \rho(\mathbf{x}). \qquad (15.1.5.21)$$

Starting from a trial solution of $\delta\rho_0(\mathbf{x}) = \mathbf{0}$, the initial residual vector is

$$\begin{aligned}\mathbf{r}_0(\mathbf{x}) = {} & (2/V)\rho(\mathbf{x})\sum_{\mathbf{h}}\theta(\bar{\mathbf{h}})\Delta F(\mathbf{h})\exp(-2\pi i\mathbf{hx})\\ & - \Delta\rho(\mathbf{x}) + \Delta H(\mathbf{x}),\end{aligned} \qquad (15.1.5.22)$$

where

$$\Delta F(\mathbf{h}) = F(\mathbf{h}) - \theta(\mathbf{h})G(\mathbf{h}), \qquad (15.1.5.23)$$

$$G(\mathbf{h}) = (V/N)\sum_{\mathbf{y}}\rho^2(\mathbf{y})\exp(2\pi i\mathbf{hy}) \qquad (15.1.5.24)$$

and

$$\Delta\rho(\mathbf{x}) = (1/V)\sum_{\mathbf{h}}\Delta F(\mathbf{h})\exp(-2\pi i\mathbf{hx}). \qquad (15.1.5.25)$$

Thus, only three FFTs are required to calculate the initial residual. The residual of Sayre's equation is given in equation (15.1.5.23).

The calculation of $\mathbf{q}_k$ in equation (15.1.5.14) is achieved in a similar manner using FFTs,

$$\begin{aligned}\mathbf{q}_k = \mathbf{J}\mathbf{p}_k &= \left\{\begin{matrix}(1/V)\sum_{\mathbf{h}}[2a(\mathbf{h})\theta(\mathbf{h}) - b(\mathbf{h})]\exp(-2\pi i\mathbf{hx})\\ \hline p_k(\mathbf{x})\end{matrix}\right\}\\ &= \left[\begin{matrix}Q_k(\mathbf{x})\\ \hline p_k(\mathbf{x})\end{matrix}\right],\end{aligned} \qquad (15.1.5.26)$$

where the vector is partitioned as shown above, and

$$a(\mathbf{h}) = (V/N)\sum_{\mathbf{y}}\rho(\mathbf{y})p_k(\mathbf{y})\exp(2\pi i\mathbf{hy}), \qquad (15.1.5.27)$$

$$b(\mathbf{h}) = (V/N)\sum_{\mathbf{y}} p_k(\mathbf{y})\exp(2\pi i\mathbf{hy}). \qquad (15.1.5.28)$$

Similarly, vector $\mathbf{s}_k$ in equation (15.1.5.16) is obtained from

$$\begin{aligned}\mathbf{s}_k = \mathbf{J}^T\mathbf{q}_k = {} & (2/V)\rho(\mathbf{x})\sum_{\mathbf{h}}\theta(\bar{\mathbf{h}})[2a(\mathbf{h})\theta(\mathbf{h}) - b(\mathbf{h})]\exp(-2\pi i\mathbf{hx})\\ & -Q_k(\mathbf{x}) + p_k(\mathbf{x}),\end{aligned} \qquad (15.1.5.29)$$

where $Q_k(\mathbf{x})$ is defined in equation (15.1.5.26).

The remaining calculations in equations (15.1.5.12), (15.1.5.13), (15.1.5.15), (15.1.5.17) and (15.1.5.18) require either the inner product of a pair of vectors or a linear combination of vectors, both of which are very quick to calculate. Each iteration of the conjugate gradient requires four FFTs, as described in equations (15.1.5.26)–(15.1.5.29).

15.1.5.2.3. The diagonal approximation

The full-matrix solution to equation (15.1.5.4) requires a significant amount of computing, although it can be achieved using FFTs. The diagonal approximation to the normal matrix has been used as an alternative method of solution to the electron-density shift in equation (15.1.5.4) (Main, 1990*b*). As with the full-matrix calculation, it can be done entirely by FFTs and a linear combination of vectors.

The diagonal element of the normal matrix, $\mathbf{J}^T\mathbf{J}$, in equation (15.1.5.7) is

$$d_0(\mathbf{x}) = (4/N)\rho(\mathbf{x})\left[\rho(\mathbf{x})\sum_{\mathbf{h}}|\theta(\mathbf{h})|^2 - \sum_{\mathbf{h}}\theta(\mathbf{h})\right] + 2. \qquad (15.1.5.30)$$

The right-hand side of equation (15.1.5.7), $-\mathbf{J}^T\varepsilon(\mathbf{x})$, is identical to the residual vector, $r_0(\mathbf{x})$, which can be calculated from equation (15.1.5.22). Therefore, the solution to the electron-density shift, $\delta\rho(\mathbf{x})$, can be calculated from

$$\delta\rho(\mathbf{x}) = r_0(\mathbf{x})/d_0(\mathbf{x}). \qquad (15.1.5.31)$$

Compared with the full-matrix solution, all the calculations involved in between equations (15.1.5.12) and (15.1.5.18) and the subsequent iterations are spared in the diagonal approximation. This makes calculation by the diagonal approximation much faster than by the full-matrix method.

15.1.6. Statistical density-modification methods

Statistical density-modification methods arise from a reinterpretation of the problem of phase improvement in statistical terms, and as a result reduce the problems of bias associated with the classical density-modification methods described above.

This is achieved by expressing all information about probable electron-density values in the map in terms of probability distributions, with a probability distribution of electron-density values assigned to each point in the electron-density map. The probable electron-density values at any point in the map may depend, for example, on whether that point lies in the solvent or protein region, and on any NCS relationships with other regions of the map. These distributions are then used to infer corresponding phase probability distributions in reciprocal space, which may then be combined with any existing phase information. This avoids working with a single map representing a single sample from the phase probability distributions.

This formulation in turn weakens the link between the newly introduced information and the initial phase probability distributions, thus reducing the bias introduced in a single cycle of phase improvement. Since the current 'best' map is not used as a starting map to be modified, the phase probability distributions from which the 'best' map is derived are not directly included in any new phase information. The only way in which the current phases are used is in the classification of the asymmetric unit into regions of different density types, *e.g.* solvent and protein.

The result of these changes is that statistical density-modification techniques lead to reduced phase bias and more realistic estimates of the figures of merit. The resulting method has been implemented in the *RESOLVE* software (Terwilliger, 1999). In addition to its application to conventional density-modification problems, it has been particularly effective in removing bias from maps phased from an atomic model through the 'prime-and-switch' approach (Terwilliger, 2004). The statistical approach to density modification requires substantially more computation that the simpler classical methods.

15.1.7. Example

To demonstrate the effect of different constraints on phase improvement, various density-modification techniques were applied to an MIR data set for which the refined structure coordinates are available. The test structure is 5-carboxymethyl-2-hydroxymuconate isomerase, solved by Wigley *et al.* (1989). MIR phases were available to 3.7 Å, with SIR information to 2.6 Å. Density modification was used to improve and extend phases to the limit of the data at 2.1 Å. The structure includes threefold noncrystallographic symmetry.

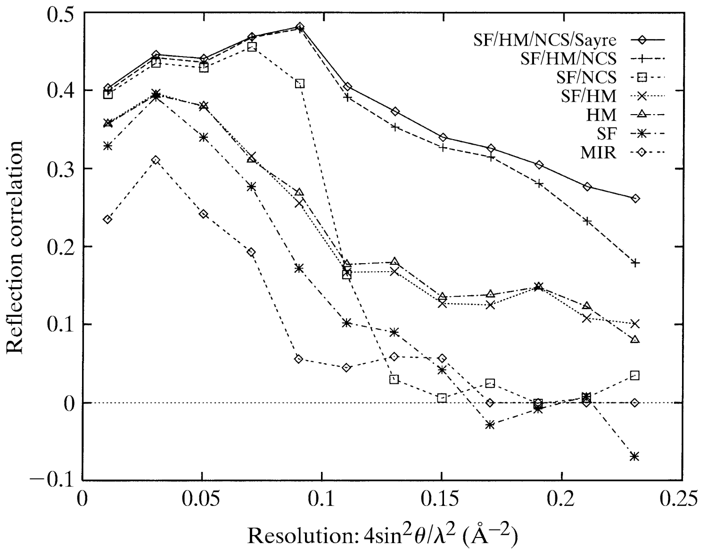


Figure 15.1.7.1

Phase correlations after different combinations of density modifications.

The MIR and density-modified phases are compared by plotting the mean of the cosine of the phase error, weighted by the figure of merit and structure-factor amplitude, as a function of resolution (Zhang *et al.*, 1997),

$$C_f = \langle w|F|^2\cos(\varphi - \varphi_0)\rangle / \left(\langle w^2|F|^2\rangle\langle|F|^2\rangle\right)^{1/2}. \qquad (15.1.7.1)$$

This phase correlation over all reflections is equivalent to map correlation. The results of density modification by various techniques, using the reflection-omit method for phase combination, are shown in Fig. 15.1.7.1.

Solvent flattening alone has slightly improved the phases at low resolution but has not lead to significant phase extension. The solvent-flattening function in Fig. 15.1.3.1 only has nonzero amplitudes close to the origin. It relates structure factors only in a very thin resolution shell. Therefore, solvent flattening is weak on phase extension.

Histogram matching alone improves the low-resolution phases and gives significant phase extension to higher resolutions. The histogram-matching function in Fig. 15.1.3.1 showed much stronger high-resolution amplitudes. Therefore, it could relate structure factors in a larger resolution shell. Moreover, there is always an ideal histogram specified at a given target resolution for phase extension. These two reasons combined make histogram matching a more powerful technique in phase extension than solvent flattening.

The combination of histogram matching and solvent flattening is slightly more powerful than histogram matching alone; since histogram matching sharpens the protein density, it implies an element of solvent flattening. Solvent flattening and averaging give a significant improvement at low resolution, but little phase extension. Averaging is powerful for phase refinement, but is weak for phase extension if no special precautions are taken. If there are flexible loop regions on the protein surface, these regions should be excluded from the molecular mask for averaging. The phasing power of averaging weakens at high resolution when the differences between NCS-related molecules become significant. Solvent flattening, histogram matching and averaging combined give a dramatic improvement at all resolutions. The addition of Sayre's equation gives a slight further improvement at high resolution.

Sayre's equation is very effective for phase refinement and extension at atomic or near atomic resolution. It becomes ineffective at low resolution or when the initial map is poor. Under these circumstances, it is better to apply other density-modification methods first to refine the phases and extend them to a higher resolution before Sayre's equation is applied. Sayre's equation also decreases in power as the solvent content increases, since it is only applicable to the protein regions of the map.

The fact that the best results were obtained when all the constraints were combined indicates that each constraint contains some degree of independent phasing information. Moreover, it also suggests that the strengths of these constraints are complementary. Each constraint, when applied in isolation, may introduce systematic errors that are difficult to overcome when a different constraint is subsequently applied. This problem is greatly reduced when the constraints are applied simultaneously and the combined process iterates much further towards the desired density map.

Density-modification methods have become sufficiently powerful that it is possible to solve structures from comparatively poor initial maps. This has reduced the amount of effort required to find more heavy-atom derivatives and to collect additional diffraction data sets. Density modification may simplify the process of map interpretation, even when good phase information is available. Density modification can also be used to obtain phases *ab initio* when high-order noncrystallographic symmetry is present.

Chapter 15.2. Model phases: probabilities, bias and maps

R. J. Read

15.2.1. Introduction

The intensities of X-ray diffraction spots measured from a crystal give us only the amplitudes of the diffracted waves. To reconstruct a map of the electron density in the crystal, the unmeasured phase information is also required. In fact, the phases are much more important to the appearance of the map than the measured amplitudes. When phases are supplied by an atomic model, therefore, some degree of model bias is inevitable.

The optimal use of model phase information requires an estimate of its reliability, specifically the probability that various values of the phase angle are true. Such a probability distribution can be derived, starting first with the relationship between the structure factor (amplitude and phase) of the model and that of the true crystal structure. The phase probability distribution can then be obtained from this and used, for instance, to provide a figure-of-merit weighting that minimizes the r.m.s. error from the true electron density.

Even with figure-of-merit weighting, model-phased electron density is biased towards the model. The systematic bias component of model-phased map coefficients can be predicted, allowing the derivation of map coefficients that give electron-density maps with reduced model bias. With the help of a few simple assumptions, a correction for bias can also be made when different sources of phase information are combined.

Finally, the refinement of a model against the observed amplitudes allows a certain amount of overfitting of the data, which leads to an extra 'refinement bias'. Fortunately, the use of appropriate refinement strategies, including maximum-likelihood targets, can reduce the severity of this problem.

15.2.2. Model bias: importance of phase

Dramatic illustrations of the importance of the phase have been published. For instance, Ramachandran & Srinivasan (1961) calculated an electron-density map using phases from one structure and amplitudes from another. In this map there were peaks at the positions of the atoms in the structure that contributed the phase information, but not in the structure that contributed the amplitudes. Similar calculations with two-dimensional Fourier transforms of photographs (Oppenheim & Lim, 1981; Read, 1997) showed that the phases of one completely overwhelmed the amplitudes of the other.

These examples, though dramatic, are not completely representative of the normal situation, where the structure contributing the phases is partially or even nearly correct. Nonetheless, model phases always contribute bias, so that the resulting map tends to bear too close a resemblance to the model.

15.2.2.1. Parseval's theorem

The importance of the phase can be understood most easily in terms of Parseval's theorem, a result that is important to the understanding of many aspects of the Fourier transform and its use in crystallography. Parseval's theorem states that the mean-square value of the variable on one side of a Fourier transform is proportional to the mean-square value of the variable on the other side. Since the Fourier transform is additive, Parseval's theorem also applies to sums or differences.

If ρ_1 and ρ_2 are, for instance, the true electron density and the electron density of the model, respectively, Parseval's theorem tells us that the r.m.s. error in the electron density is proportional to the r.m.s. error in the structure factor. (The structure-factor error is a vector error in the complex plane.)

$$\langle \rho^2 \rangle = (1/V^2) \sum_{\text{all } \mathbf{h}} |\mathbf{F}(\mathbf{h})|^2,$$

$$\left\langle (\rho_1 - \rho_2)^2 \right\rangle = (1/V^2) \sum_{\text{all } \mathbf{h}} |\mathbf{F}_1(\mathbf{h}) - \mathbf{F}_2(\mathbf{h})|^2.$$

This understanding of error in electron-density maps explains why the phase is much more important than the amplitude in determining the appearance of an electron-density map. As illustrated in Fig. 15.2.2.1, a random choice of phase (from a uniform distribution of all possible phases) will generally give a larger error in the complex plane than a random choice of amplitude [from a Wilson (1949) distribution of amplitudes].

15.2.3. Structure-factor probability relationships

To use model phase information optimally, the probability distribution for the true phase (or, equivalently, the distribution of the error in the model phase) needs to be known. Such a distribution can be derived by first working out the probability distribution for the true structure factor (or the distribution of the vector difference between the model and true structure factors). Then the phase probability distribution is obtained by fixing the known value of the structure-factor amplitude and renormalizing.

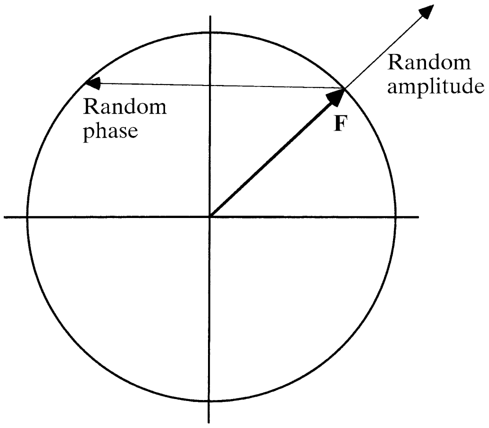

Figure 15.2.2.1
Schematic illustration of the relative errors introduced by a random choice of phase or a random choice of amplitude. The example has been constructed to represent the r.m.s. errors introduced by randomization (computed by averages over the Wilson distribution). Phase randomization will introduce r.m.s. errors of $(2)^{1/2}$ ($\simeq 1.41$) times the r.m.s. structure-factor amplitude $|\mathbf{F}|$. By comparison, map coefficients weighted by figures of merit of zero would have r.m.s. errors equal to the r.m.s. $|\mathbf{F}|$, so a featureless map would be more accurate than a random-phase map. Amplitude randomization will introduce r.m.s. errors of $[(4-\pi)/2]^{1/2}$ ($\simeq 0.66$) times the r.m.s. $|\mathbf{F}|$, so a map computed with random amplitudes will be closer to the true map than a featureless map.

Copyright © 2012 International Union of Crystallography

A number of related structure-factor distributions have been derived, differing in the amount of information available about the structure and in the assumed form of errors in the model. These range from the Wilson distribution, which applies when none of the atomic positions is known, to a distribution that applies when there are a variety of sources of error in an atomic model.

15.2.3.1. Wilson and Sim structure-factor distributions in P1

For the Wilson distribution (Wilson, 1949), it is assumed that the atoms in a crystal structure in space group $P1$ are scattered randomly and independently through the unit cell. In fact, it is sufficient to make the much less restrictive assumption that the atoms are placed randomly with respect to the Bragg planes defined by the Miller indices. The assumption of independence is somewhat more problematic, since there are restrictions on the distances between atoms, large volumes of protein crystals are occupied by disordered solvent and many protein crystals display noncrystallographic symmetry; as discussed elsewhere (Vellieux & Read, 1997; Kleywegt & Read, 1997), the resulting relationships among structure factors are exploited implicitly in averaging and solvent-flattening procedures. The higher-order relationships among structure factors are used explicitly in direct methods for solving small-molecule structures and are being developed for use in protein structures (Bricogne, 1993). For the purposes of simpler relationships between the calculated and true structure factors for a single *hkl*, however, the lack of complete independence does not seem to create serious problems.

When atoms are placed randomly relative to the Bragg planes, the contribution of each atom to the structure factor will have a phase varying randomly from 0 to 2π. The overall structure factor can then be considered to be the result of a random walk in the complex plane, which can be treated as an application of the central limit theorem. The structure factor is the sum of the independent atomic scattering contributions, each of which has a probability distribution defined as a circle in the complex plane centred on the origin, with a radius of f_j. The centroid of this atomic distribution is at the origin, and the variance for each of the real and imaginary parts is $\frac{1}{2}f_j^2$. The probability distribution of the structure factor that is the sum of these contributions is a two-dimensional Gaussian, the product of the one-dimensional Gaussians for the real and imaginary parts. Because the variances are equal in the real and imaginary directions, it can be simplified, as shown below, and expressed in terms of a single distribution parameter, Σ_N. Alternatively, and more simply, the structure-factor probability distribution can be considered as a complex normal distribution, arising from application of the central limit theorem to complex variables (Read, 2003).

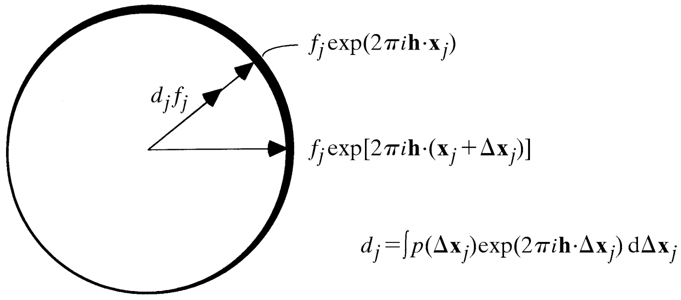
$$\mathbf{F} = \sum_{j=1}^{N} f_j \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_j) = A + iB; \quad \langle A\rangle = \langle B\rangle = 0;$$

$$\sigma^2(A) = \sigma^2(B) = \tfrac{1}{2}\sum_{j=1}^{N} f_j^2 = \tfrac{1}{2}\Sigma_N, \text{ so}$$

$$\begin{aligned} p(A) &= [1/(\pi\Sigma_N)^{1/2}]\exp\left(-A^2/\Sigma_N\right),\\ p(B) &= [1/(\pi\Sigma_N)^{1/2}]\exp\left(-B^2/\Sigma_N\right),\\ p(\mathbf{F}) = p(A,B) &= (1/\pi\Sigma_N)\exp\left(-|\mathbf{F}|^2/\Sigma_N\right). \end{aligned}$$

The Sim distribution (Sim, 1959), which is relevant when the positions of some of the atoms are known, has a very similar basis, except that the structure factor is now considered to arise from a random walk starting from the position of the structure factor corresponding to the known part, $\mathbf{F}_P$. Atoms with known positions do not contribute to the variance, while each of the atoms with unknown positions (the 'Q' atoms) contributes $\frac{1}{2}f_j^2$ to each of the real and imaginary parts, as in the Wilson distribution. The distribution parameter in this case is referred to as Σ_Q. The Sim distribution is a conditional probability distribution, depending on the value of $\mathbf{F}_P$,

$$p(\mathbf{F};\mathbf{F}_P) = (1/\pi\Sigma_Q)\exp\left(-|\mathbf{F}-\mathbf{F}_P|^2/\Sigma_Q\right).$$



$f_j\exp(2\pi i\mathbf{h}\cdot\mathbf{x}_j)$
$d_j f_j$
$f_j\exp[2\pi i\mathbf{h}\cdot(\mathbf{x}_j+\Delta\mathbf{x}_j)]$
$d_j=\int p(\Delta\mathbf{x}_j)\exp(2\pi i\mathbf{h}\cdot\Delta\mathbf{x}_j)\,\mathrm{d}\Delta\mathbf{x}_j$

Figure 15.2.3.1
Centroid of the structure-factor contribution from a single atom. The probability of a phase for the contribution is indicated by the thickness of the line.

The Wilson (1949) and Woolfson (1956) distributions for space group $P\bar{1}$ are obtained similarly, except that the random walks are along a line and the resulting Gaussian distributions are one-dimensional. (The Woolfson distribution is the centric equivalent of the Sim distribution.) For more complicated space groups, it is reasonable to assume that acentric reflections follow the $P1$ distribution and that centric reflections follow the $P\bar{1}$ distribution. However, for any zone of the reciprocal lattice in which symmetry-related atoms are constrained to scatter in phase, the variances must be multiplied by the expected intensity factor, ε, for the zone, because the symmetry-related contributions are no longer independent.

15.2.3.2. Probability distributions for variable coordinate errors

In the Sim distribution, an atom is considered to be either exactly known or completely unknown in its position. These are extreme cases, since there will normally be varying degrees of uncertainty in the positions of various atoms in a model. The treatment can be generalized by allowing a probability distribution of coordinate errors for each atom. In this case, the centroid for the individual atomic contribution to the structure factor will no longer be obtained by multiplying by either zero or one. Averaged over the circle corresponding to possible phase errors, the centroid will generally be reduced in magnitude, as illustrated in Fig. 15.2.3.1. In fact, averaging to obtain the centroid is equivalent to weighting the atomic scattering contribution by the Fourier transform of the coordinate-error probability distribution, d_j. By the convolution theorem, this in turn is equivalent to convoluting the atomic density with the coordinate-error distribution. Intuitively, the atom is smeared over all of its possible positions. The weighting factor, d_j, is thus analogous to the thermal-motion term in the structure-factor expression.

The variances for the individual atomic contributions will differ in magnitude, but if there are a sufficient number of independent sources of error, we can invoke the central limit theorem again and assume that the probability distribution for the structure factor will be a Gaussian centred on $\sum d_j f_j \exp\left(2\pi i\mathbf{h}\cdot\mathbf{x}_j\right)$. If the coordinate-error distribution is Gaussian, and if each atom in the model is subject to the same

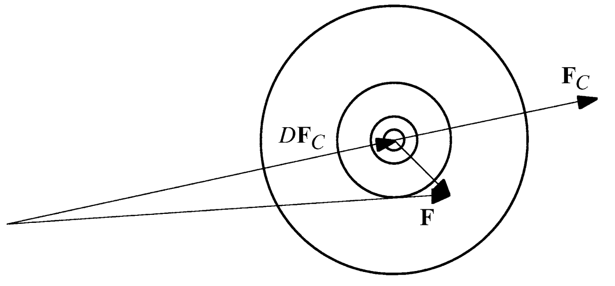


Figure 15.2.3.2
Schematic illustration of the general structure-factor distribution, relevant in the case of any set of independent random errors in the atomic model.

errors, the resulting structure-factor probability distribution is the Luzzati (1952) distribution. In this special case, $d_j = D$ for all atoms, where D is the Fourier transform of a Gaussian and behaves like the application of an overall B factor.

15.2.3.3. *General treatment of the structure-factor distribution*

The Wilson, Sim, Luzzati and variable-error distributions have very similar forms, because they are all Gaussians arising from the application of the central limit theorem. The central limit theorem is valid under many circumstances; even when there are errors in position, scattering factor and B factor, as well as missing atoms, a similar distribution still applies. As long as these sources of error are independent, the true structure factor will have a Gaussian distribution centred on $D\mathbf{F}_C$ (Fig. 15.2.3.2), where D now includes effects of all sources of error, as well as compensating for errors in the overall scale and B factor (Read, 1990).

$$p(\mathbf{F}; \mathbf{F}_C) = (1/\pi\varepsilon\sigma_\Delta^2)\exp\left(-|\mathbf{F} - D\mathbf{F}_C|^2/\varepsilon\sigma_\Delta^2\right)$$

in the acentric case, where $\sigma_\Delta^2 = \Sigma_N - D^2\Sigma_P$, ε is the expected intensity factor and Σ_P is the Wilson distribution parameter for the model.

For centric reflections, the scattering differences are distributed along a line, so the probability distribution is a one-dimensional Gaussian.

$$p(\mathbf{F}; \mathbf{F}_C) = [1/(2\pi\varepsilon\sigma_\Delta^2)^{1/2}]\exp\left(-|\mathbf{F} - D\mathbf{F}_C|^2/2\varepsilon\sigma_\Delta^2\right).$$

15.2.3.4. *Estimating σ_A*

Srinivasan (1966) showed that the Sim and Luzzati distributions could be combined into a single distribution that had a particularly elegant form when expressed in terms of normalized structure factors, or E values. This functional form still applies to the general distribution that reflects a variety of sources of error; the only difference is the interpretation placed on the parameters (Read, 1990). If $\mathbf{F}$ and $\mathbf{F}_C$ are replaced by the corresponding E values, a parameter σ_A plays the role of D, and σ_Δ^2 reduces to $(1 - \sigma_A^2)$. [The parameter σ_A is equivalent to D after correction for model completeness; $\sigma_A = D(\Sigma_P/\Sigma_N)^{1/2}$.] When the structure factors are normalized, overall scale and B-factor effects are also eliminated. The parameter σ_A that characterizes this probability distribution varies as a function of resolution. It must be deduced from the amplitudes $|\mathbf{F}_O|$ and $|\mathbf{F}_C|$, since the phase (thus the phase difference) is unknown.

A general approach to estimating parameters for probability distributions is to maximize a likelihood function. The likelihood function is the overall joint probability of making the entire set of observations, which is a function of the desired parameters. The parameters that maximize the probability of making the set of observations are the most consistent with the data. The idea of using maximum likelihood to estimate model phase errors was introduced by Lunin & Urzhumtsev (1984), who gave a treatment that was valid for space group $P1$. In a more general treatment that applies to higher-symmetry space groups, allowance is made for the statistical effects of crystal symmetry (centric zones and differing expected intensity factors) (Read, 1986).

The σ_A values are estimated by maximizing the joint probability of making the set of observations of $|\mathbf{F}_O|$. If the structure factors are all assumed to be independent, the joint probability distribution is the product of all the individual distributions. The assumption of independence is not completely justified in theory, but the results are fairly accurate in practice.

$$L = \prod_{\mathbf{h}} p(|\mathbf{F}_O|; |\mathbf{F}_C|).$$

The required probability distribution, $p(|\mathbf{F}_O|; |\mathbf{F}_C|)$, is derived from $p(\mathbf{F}_O; \mathbf{F}_C)$ by integrating over all possible phase differences. The form of this distribution, which is given in other publications (Read, 1986, 1990), differs for centric and acentric reflections. (It is important to note that although the distributions for structure factors are Gaussian, the distributions for amplitudes obtained by integrating out the phase are not.) It is more convenient to deal with a sum than a product, so the log likelihood function is maximized instead. In the program *SIGMAA*, reciprocal space is divided into spherical shells, and a value of the parameter σ_A is refined for each resolution shell. Details of the algorithm are given elsewhere (Read, 1986).

The resolution shells must be thick enough to contain several hundred to a thousand reflections each, in order to provide σ_A estimates with a sufficiently small statistical error. A larger number of shells (fewer reflections per shell) can be used for refined structures, since estimates of σ_A become more precise as the true value approaches 1. If there are sufficient reflections per shell, the estimates will vary smoothly with resolution. As discussed below, the smooth variation with resolution can also be exploited through a restraint that allows σ_A values to be estimated from fewer reflections.

15.2.3.5. *Accounting for measurement errors*

For unrefined models, the disagreement between the true and calculated structure factors is dominated by the effect of defects in the model, so that the effect of errors in measuring the observed intensities or amplitudes can be neglected (Read, 1986). As the model improves, the effect of measurement error becomes relevant. Three approaches have been used to account for measurement error. In one approach, first proposed by Green (1979) in the context of isomorphous replacement, measurement error is treated as a complex error, and the variance term, σ, is increased accordingly (Murshudov *et al.*, 1997; Bricogne & Irwin, 1996). This has the virtue of simplicity and it works well. Another approach is to use a Gaussian approximation to the likelihood function expressed in terms of amplitudes, and then increase the variance of this Gaussian (Pannu & Read, 1996). Finally, the convolution of the likelihood function (expressed in intensities) and a Gaussian measurement error can be evaluated by using a series approximation (Pannu & Read, 1996). This has the benefit that it allows for the presence of negative net intensity measurements, but it is more complicated to implement and is not widely used.

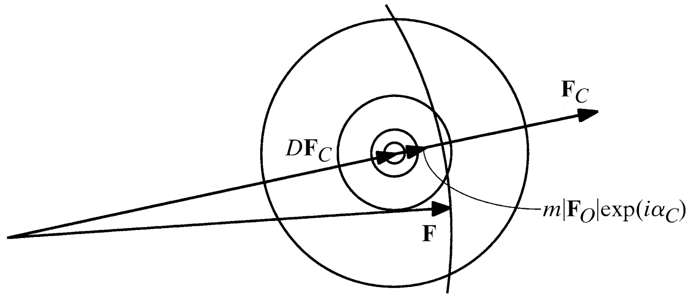

Figure 15.2.4.1
Figure-of-merit weighted model-phased structure factor, obtained as the probability-weighted average over all possible phases.

15.2.4. Figure-of-merit weighting for model phases

Blow & Crick (1959) and Sim (1959) showed that the electron-density map with the least r.m.s. error is calculated from centroid structure factors. This conclusion follows from Parseval's theorem, because the centroid structure factor (its probability-weighted average value or expected value) minimizes the r.m.s. error of the structure factor. Since the structure-factor distribution $p(\mathbf{F};\,\mathbf{F}_C)$ is symmetrical about $\mathbf{F}_C$, the expected value of $\mathbf{F}$ will have the same phase as $\mathbf{F}_C$, but the averaging around the phase circle will reduce its magnitude if there is any uncertainty in the phase value (Fig. 15.2.4.1). We treat the reduction in magnitude by applying a weighting factor called the figure of merit, m, which is equivalent to the expected value of the cosine of the phase error.

15.2.5. Map coefficients to reduce model bias

15.2.5.1. Model bias in figure-of-merit weighted maps

A figure-of-merit weighted map, calculated with coefficients $m|\mathbf{F}_O|\exp(i\alpha_C)$, has the least r.m.s. error from the true map. According to the normal statistical (minimum variance) criteria, then, it is the best map. However, such a map will suffer from model bias; if its purpose is to allow the detection and repair of errors in the model, this is a serious qualitative defect. Fortunately, it is possible to predict the systematic errors leading to model bias and to make some correction for them.

Main (1979) dealt with this problem in the case of a perfect partial structure. Since the relationships among structure factors are the same in the general case of a partial structure with various errors, once $D\mathbf{F}_C$ is substituted for $\mathbf{F}_C$, all that is required to apply Main's results more generally is a change of variables (Read, 1986, 1990).

In Main's approach, the cosine law is used to introduce the cosine of the phase error, which is converted into a figure of merit by taking expected values. Some manipulations allow us to solve for the figure-of-merit weighted map coefficient, which is approximated as a linear combination of the true structure factor and the model structure factor (Main, 1979; Read, 1986). Finally, we can solve for an approximation to the true structure factor, giving map coefficients from which the systematic model bias component has been removed.

$$m|\mathbf{F}_O|\exp(i\alpha_C) = F/2 + D\mathbf{F}_C/2 + \text{noise terms},$$
$$F \simeq (2m|\mathbf{F}_O| - D|\mathbf{F}_C|)\exp(i\alpha_C).$$

A similar analysis for centric structure factors shows that there is no systematic model bias in figure-of-merit weighted map coefficients, so no bias correction is needed in the centric case.

15.2.5.2. Model bias in combined phase maps

When model phase information is combined with, for instance, multiple isomorphous replacement (MIR) phase information, there will still be model bias in the acentric map coefficients, to the extent that the model influences the final phases. However, it is inappropriate to continue using the same map coefficients to reduce model bias, because some phases could be determined almost completely by the MIR phase information. It makes much more sense to have map coefficients that reduce to the coefficients appropriate for either model or MIR phases, in extreme cases where there is only one source of phase information, and that vary smoothly between those extremes.

Map coefficients that satisfy these criteria (even if they are not rigorously derived) are implemented in the program *SIGMAA*. The resulting maps are reasonably successful in reducing model bias. Two assumptions are made: (1) the model-bias component in the figure-of-merit weighted map coefficient, $m_{\rm com}|\mathbf{F}_O|\exp(i\alpha_{\rm com})$, is proportional to the influence that the model phase has had on the combined phase; and (2) the relative influence of a source of phase information can be measured by the information content, H (Guiasu, 1977), of the phase probability distribution. The first assumption corresponds to the idea that the figure-of-merit weighted map coefficient is a linear combination of the MIR and model phase cases.

$$\begin{array}{lll} \text{MIR:} & m_{\rm MIR}|\mathbf{F}_O|\exp(i\alpha_{\rm MIR}) & \simeq \mathbf{F} \\ \text{Model:} & m_C|\mathbf{F}_O|\exp(i\alpha_C) & \simeq \mathbf{F}/2 + D\mathbf{F}_C/2 \\ \text{Combined:} & m_{\rm com}|\mathbf{F}_O|\exp(i\alpha_{\rm com}) & \simeq [1-(w/2)]\mathbf{F} + (w/2)D\mathbf{F}_C, \end{array}$$

where

$$w = H_C/(H_C + H_{\rm MIR})$$

and

$$H = \int\limits_0^{2\pi} p(\alpha)\ln\frac{p(\alpha)}{p_0(\alpha)}\,{\rm d}\alpha; \qquad p_0(\alpha) = \frac{1}{2\pi}.$$

Solving for an approximation to the true $\mathbf{F}$ gives the following expression, which can be seen to reduce appropriately when w is 0 (no model influence) or 1 (no MIR influence):

$$\mathbf{F} \simeq \frac{2m|\mathbf{F}_O|\exp(i\alpha_{\rm com}) - wD\mathbf{F}_C}{2-w}.$$

15.2.6. Estimation of overall coordinate error

In principle, since the distribution of observed and calculated amplitudes is determined largely by the coordinate errors of the model, one can determine whether a particular coordinate-error distribution is consistent with the amplitudes. Unfortunately, it turns out that the coordinate errors cannot be deduced unambiguously, because many distributions of coordinate errors are consistent with a particular distribution of amplitudes (Read, 1990).

If the simplifying assumption is made that all the atoms are subject to a single error distribution, then the parameter D (and thus the related parameter σ_A) varies with resolution as the Fourier transform of the error distribution, as discussed above. Two related methods to estimate overall coordinate error are based on the even more specific assumption that the coordinate-error distribution is Gaussian: the Luzzati plot (Luzzati, 1952) and the σ_A plot (Read, 1986). Unfortunately, the central assumption is not justified; atoms that scatter more strongly (heavier atoms or atoms with lower B factors) tend to have smaller coordinate errors than weakly scattering atoms. The proportion of the structure factor contributed by well ordered atoms increases at high resolution, so that the structure factors agree better at high resolution than if there were a single error distribution.

It is often stated, optimistically, that the Luzzati plot provides an upper bound to the coordinate error, because the observation errors in $|\mathbf{F}_O|$ have been ignored. This is misleading, because there are other effects that cause the Luzzati and σ_A plots to give underestimates (Read, 1990). Chief among these are the correlation of errors and scattering power and the overfitting of the amplitudes in structure refinement (discussed below). These estimates of overall coordinate error should not be interpreted too literally; at best, they provide a comparative measure.

15.2.7. Difference-map coefficients

The computer program *SIGMAA* (Read, 1986) has been developed to implement the results described here. Apart from the two types of map coefficient discussed above, two types of difference-map coefficient can also be produced:

(1) Model-phased difference map: $(m|\mathbf{F}_O| - D|\mathbf{F}_C|)\exp(i\alpha_C)$;
(2) General difference map: $m_{\rm com}|\mathbf{F}_O|\exp(i\alpha_{\rm com}) - D\mathbf{F}_C$.

The general difference map, it should be noted, uses a vector difference between the figure-of-merit weighted combined phase coefficient (the 'best' estimate of the true structure factor) and the calculated structure factor. When additional phase information is available, it should provide a clearer picture of the errors in the model.

Similar algorithms have been implemented as part of modern refinement programs such as *Refmac* (Murshudov *et al.*, 1997) and *phenix.refine* (Afonine *et al.*, 2005).

15.2.8. Refinement bias

The structure-factor probabilities discussed above depend on the atoms having independent errors (or at least a sufficient number of groups of atoms having independent errors). Unfortunately, this assumption breaks down when a structure is refined against the observed diffraction data. Few protein crystals diffract to sufficiently high resolution to provide a large number of observations for every refinable parameter. The refinement problem is, therefore, not sufficiently overdetermined, so it is possible to overfit the data. If there is an error in the model that is outside the range of convergence of the refinement method, it is possible to introduce compensating errors in the rest of the structure to give a better, and misleading, agreement in the amplitudes. As a result, the phase accuracy (hence the weighting factors m and D) is overestimated, and model bias is poorly removed.

There is another interpretation to the problem of refinement bias. As Silva & Rossmann (1985) point out, minimizing the r.m.s. difference between the amplitudes $|\mathbf{F}_O|$ and $|\mathbf{F}_C|$ is equivalent (by Parseval's theorem) to minimizing the difference between the model electron density and the density corresponding to the map coefficients $|\mathbf{F}_O|\exp(i\alpha_C)$; a lower residual is obtained either by making the model look more like the true structure, or by making the model-phased map look more like the model through the introduction of systematic phase errors.

A number of strategies are available to reduce the degree or impact of refinement bias. The overestimation of phase accuracy can be avoided by obtaining unbiased estimates of the σ_A values from the cross-validation data, which were originally introduced to compute $R_{\rm free}$ as an unbiased indicator of refinement progress (Brünger, 1992). Because of the high statistical error of σ_A estimates computed from small numbers of reflections, reliable values can only be obtained by exploiting the smoothness of the σ_A curve as a function of resolution. This can be achieved either by fitting a functional form (as done in *Refmac*; Murshudov *et al.*, 1997) or by adding a penalty to points that deviate from the line connecting their neighbours (as done in *CNS*; Brunger *et al.*, 1998).

If errors are suspected in certain parts of the structure, 'omit refinement' (in which the questionable parts are omitted from the model) can be a very effective way to eliminate refinement bias in those regions (James *et al.*, 1980; Hodel *et al.*, 1992).

If MIR or MAD (multiwavelength anomalous dispersion) phases are available, combined phase maps tend to suffer less from refinement bias, depending on the extent to which the experimental phases influence the combined phases. Finally, it is always a good idea to refer occasionally to the original MIR or MAD map, which cannot suffer at all from model bias or refinement bias.

This chapter is a revised version of a contribution to *Methods in Enzymology* (Read, 1997).

Chapter 15.3. *DM/DMMULTI* software for phase improvement by density modification

K. D. Cowtan, K. Y. J. Zhang and P. Main

15.3.1. Introduction

DM is an automated procedure for phase improvement by iterated density modification. It is used to obtain a set of improved phases and figures of merit, using as a starting point the observed diffraction amplitudes and some initial poor estimates for the phases and figures of merit. *DM* improves the phases through an alternate application of two processes: real-space electron-density modification and reciprocal-space phase combination. *DM* can perform solvent flattening, histogram matching, multi-resolution modification, averaging, skeletonization and Sayre refinement, as well as conventional or reflection-omit phase combination. Solvent and averaging masks may be input by the user or calculated automatically. Averaging operators may be refined within the program. Multiple averaging domains may be averaged using different operators.

DMMULTI is a modified version of the *DM* software that can perform density modification simultaneously across multiple crystal forms. The procedure is general, handling an arbitrary number of domains appearing in an arbitrary number of crystal forms. Initial phases may be provided for one or more crystal forms; however, improved phases are calculated in every crystal form.

DM and *DMMULTI* are distributed as a part of the *CCP4* suite of software for protein crystallography (Collaborative Computational Project, Number 4, 1994). The theoretical and algorithmic bases for the *DM* and *DMMULTI* software suites are reviewed in Chapter 15.1. In this chapter, some specific issues concerning the programs are described, including program operation, data preparation, choices of modes and code description.

15.3.2. Program operation

DM and *DMMULTI* are largely automatic; in order to perform a phase-improvement calculation only two tasks are required of the user:

(1) Provide the input data. These must include the reflection data and solvent content, and may also include averaging operators, solvent mask and averaging domain masks.
(2) Select the appropriate density modifications and the phase-combination mode to be used in the calculation.

DM and *DMMULTI* can run with the minimum input above, since the optimum choices for a whole range of parameters are set in the program defaults. For some special problems it may be useful to control the program behaviour in more detail; this is possible through a wide range of keywords to override the defaults. These are all detailed in the documentation supplied with the software.

15.3.3. Preparation of input data

Input data are provided by two routes: numerical parameters, such as solvent content and averaging operators, are included in the command file using appropriate keywords, whereas reflections and masks are referenced by giving their file names on the command line. In the simplest case; for example a solvent-flattening and histogram-matching calculation, all that is required is an initial reflection file and an estimate of the solvent content.

Use all available data: The reflection file must be in *CCP4* 'MTZ' format, and contain at least the structure-factor amplitudes, phase estimates and figures of merit. If the phase estimates are obtained from a homologous structure by molecular replacement, the figures of merit can be generated by the *SIGMAA* program (Read, 1986). When the phases are estimated using a single isomorphous derivative (SIR), it is recommended that Hendrickson–Lattman coefficients (Hendrickson & Lattman, 1970) are used to represent the phase estimate instead of the figure of merit. Hendrickson–Lattman coefficients can represent the bimodal distribution of the SIR phases, whereas the figure of merit can only represent the unimodal distribution of the average of two equally probable phase choices. It is recommended that a reflection file containing every possible reflection is used. The low-resolution data should be included since they provide a significant amount of information on the protein–solvent boundary. The high-resolution data without phase estimates should also be included since their phases can be estimated by *DM*. Phase extension can usually improve the original phases further compared to phase refinement only. Unobserved reflections are marked by a missing number flag. This is important for the preservation of the free-R reflections. It also enables *DM* to extrapolate missing reflections from density constraints and increases the phase improvement power.

The estimation of solvent content: The solvent content, $C_{\rm solv}$, can be obtained by various experimental methods, such as the solvent dehydration method and the deuterium exchange method (Matthews, 1974). It can also be estimated through

$$C_{\rm solv} = 1 - (NV_aML/V). \qquad (15.3.3.1)$$

Here, N is the total number of atoms, including hydrogen atoms, in one protein molecule. V_a is the average volume occupied by each atom, which is estimated to be approximately 10 Å^3 (Matthews, 1968). M is the number of molecules per asymmetric unit. L is the number of asymmetric units in the cell. V is the unit-cell volume. The correctly estimated solvent content should be entered in the program with the SOLC keyword, since this will be used not only to find the solvent–protein boundary but also to scale the input structure-factor amplitudes. If it is desirable to use a more conservative solvent mask in order to prevent clipping of protein densities, especially in the flexible loop regions, different solvent and protein fractions should be specified using the SOLMASK keyword.

Solvent mask: A solvent mask may be supplied; it may be used for the entire calculation or updated after several cycles. The solvent mask usually divides the cell into protein and solvent regions; however it is also possible to specify excluded regions which are unknown. If no solvent mask is supplied, it will be calculated by a modified Wang–Leslie procedure (Wang, 1985; Leslie, 1987) and updated as the phase-improvement calculation progresses.

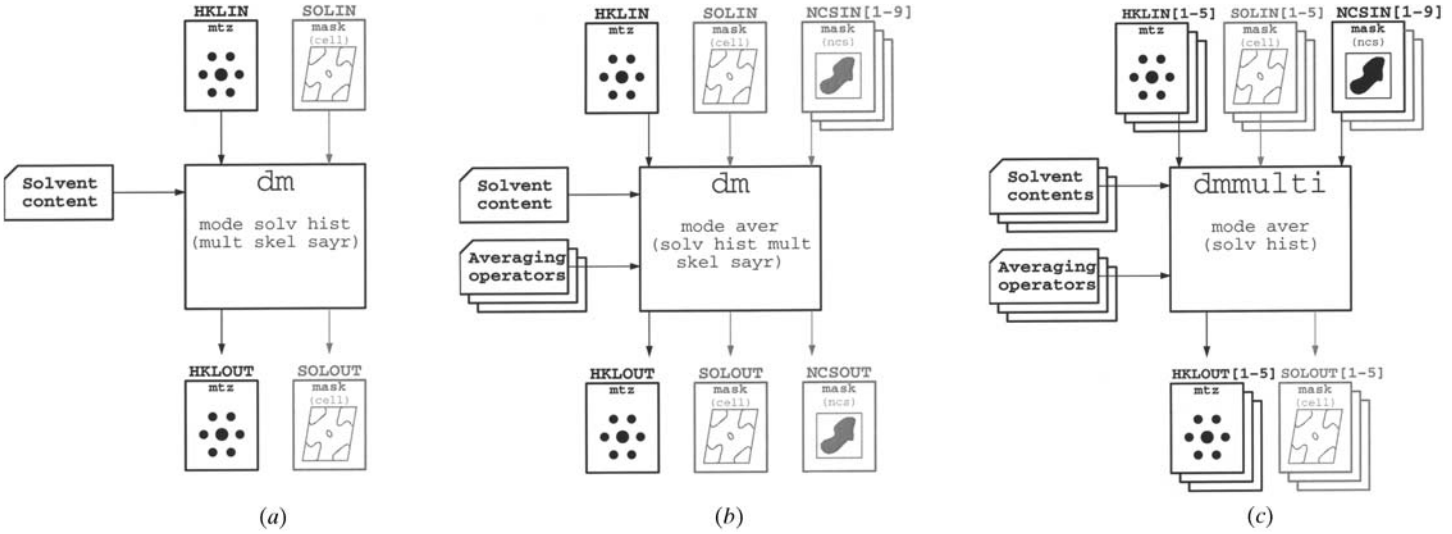

Figure 15.3.3.1

(*a*) Input and output data for a *DM* calculation with no averaging. Light outlines indicate optional information. (*b*) Input and output data for a *DM* averaging calculation: for a single averaging domain, the averaging mask may be calculated automatically. For multi-domain averaging, all domain masks must be given. (*c*) Input and output data for *DMMULTI*. An averaging mask (or masks, for multiple domains) must be provided.

Averaging operators: In an averaging calculation, the averaging operators must be supplied; these are typically obtained by rotation and translation searches using a program such as *AMoRe* (Navaza, 1994) or *X-PLOR* (Brünger, 1992). If the coordinates of several heavy atoms are known, they can be used to calculate the noncrystallographic symmetry (NCS) operators. If a partial model can be built into the density, structure-superposition programs, such as *LSQKAB* (Kabsch, 1976), can be used to obtain the rotation and translation matrices that relate different molecules in the asymmetric unit. This can also be achieved through the program *O* using the ‘lsq_explicit’ command (Jones *et al.*, 1991). The averaging operators can be further refined in *DM* by minimizing the residual between NCS related densities.

Averaging mask: An averaging mask may be supplied; this is distinct from the solvent mask, allowing for parts of the protein to remain unaveraged if required. If no averaging mask is supplied, the mask will be calculated by a local-correlation approach (Cowtan & Main, 1998; Vellieux *et al.*, 1995). If multiple domains are to be averaged with different averaging operators (Schuller, 1996), then one mask must be specified for each averaging domain. When averaging molecules related by improper NCS operations, the averaging mask must be in accord with the NCS operators provided. For example, if the supplied NCS matrix maps molecule A to molecule B, then the averaging mask must cover the volume occupied by molecule A rather than molecule B.

Multi-crystal averaging: In the case of a multi-crystal averaging calculation, one reflection file is provided for each crystal form (however, initial phases are not required in every crystal form), and one reflection file will be output for each crystal form containing the improved phases. One mask is required per averaging domain; thus, in general, only a single mask is required. This may be defined for any crystal form or in an arbitrary crystal space of its own. Averaging operators are then provided to map the mask into each of the crystal forms.

Solvent and averaging masks that are calculated within the program may be output for subsequent analysis. Refined averaging operators are also output. The input and output data for a simple *DM* calculation, a *DM* averaging calculation and a *DMMULTI* multi-crystal averaging calculation are shown in Figs. 15.3.3.1(*a*), (*b*) and (*c*), respectively.

15.3.4. Choice of modes

Two major choices have to be made in a *DM* run. They are the real-space density-modification modes and reciprocal-space phase-combination modes. Moreover, the phase-extension schemes can be selected if needed. This can also be left to the program, which uses its default automatic mode for phase extension. The choices of various modes are described in the following sections.

15.3.4.1. Density-modification modes

The following density-modification modes (specified by the MODE keyword) are provided by *DM*:

(1) Solvent flattening: This is the most common density-modification technique and is powerful for improving phases at fixed resolution, but weaker at extending phases to higher resolution. Its phasing power is highly dependent on the solvent content. Solvent flattening can be applied at comparatively low resolutions, down to around 5.0 Å.

(2) Histogram matching: This method is applied only to the density in the protein region. This method is weaker than solvent flattening for improving phases, but is much more powerful at extending phases to higher resolutions. This is due to a unique feature of histogram matching which uses a resolution-dependent target for phase improvement. The phasing power of histogram matching is inversely related to the solvent content. Therefore, histogram matching plays a more important role in phase improvement when the solvent content is low. Histogram matching works to as low as 4.0 Å, but does no harm below that. Histogram matching should probably be applied as a matter of course in any case where the structure is not dominated by a large proportion of heavy-metal atoms. Even in this case, histogram matching may be applied by defining a solvent mask with solvent, protein and excluded regions.

(3) Multi-resolution modification: This method controls the level of detail in the map as a function of resolution by applying histogram matching and solvent flattening at multiple resolutions. This strengthens phase improvement at fixed resolution, although it generally improves phase-extension calculations too.

(4) Noncrystallographic symmetry averaging: Averaging is one of the most powerful techniques available for improving phases and is applicable even at very low resolutions. In extreme cases, averaging may be used to achieve an *ab initio* structure solution (Chapman *et al.*, 1992; Tsao *et al.*, 1992). It should therefore be applied whenever it is present and the operators can be determined.
(5) Skeletonization: Iterative skeletonization is the process of tracing a 'skeleton' of connected densities through the map and then building a new map by filling density around this skeleton. The implementation in *DM* is adapted for use on poor maps, where it is sometimes but not always of use. To bring out side chains and missing loops, the *ARP* program (Lamzin & Wilson, 1997) is more suitable.
(6) Sayre's equation: This method is more widely used in small-molecule calculations, and is very powerful at better than 2.0 Å resolution and when there are no heavy atoms in the structure. However, its phasing power is lost quickly as resolution decreases beyond 2.0 Å. The calculation takes significantly longer than other density-modification modes.

The most commonly used modes are solvent flattening and histogram matching – these give a good first map in most cases. Recently, multi-resolution modification has been added to this list. Averaging is applied whenever possible. Skeletonization and Sayre's equation are generally only applied in special situations.

15.3.4.2. Phase-combination modes

Density-modification calculations are somewhat prone to producing grossly overestimated figures of merit (Cowtan & Main, 1996). Users should be aware of this. In general the phases and figures of merit produced by density-modification calculations should only be used for the calculation of weighted F_o maps. They should not be used for the calculation of difference maps or used in refinement or other calculations (the *REFMAC* program is an exception, containing a mechanism to deal with this form of bias). The use of $2F_o - F_c$-type maps should be avoided when the calculated phases are from density modification, since they are dependent on two assumptions, neither of which hold for density modification: that the current phases are very close to being correct and that the calculated amplitudes may only approach the observed values as the phase error approaches zero.

To limit the problems of overestimation, three phase-combination modes are provided (controlled by the COMBINE keyword):

(1) Free-Sim weighting: This is the simplest mode to use. Although convergence is weaker than the reflection-omit mode, the calculation never overshoots the best map. If there is averaging information, then convergence is much stronger and the phase-combination scheme is much less important. In addition, phase relationships in reciprocal space limit the effectiveness of the reflection-omit scheme. Therefore, the free-Sim weighting scheme should usually be used when there is averaging.
(2) Reflection-omit: The combination of a reciprocal-space omit procedure with *SIGMAA* phase combination (Read, 1986) leads to much better maps when applying solvent flattening and histogram matching. However, the omit calculation is computationally costly and introduces a small amount of noise into the maps, thus the phases can get worse if the calculation is run for too many cycles. A real-space free-*R* indicator (Abrahams & Leslie, 1996) is therefore used to stop the calculation at an appropriate point.
(3) Perturbation-γ correction: This new approach is an extension of the γ correction of Abrahams (1997) to arbitrary density-modification methods. The results are a good approximation to a perfect reflection-omit scheme and required considerably less computation. This is therefore the preferred mode for all calculations.

In the case of a molecular-replacement calculation or high noncrystallographic symmetry, it may be desirable only to weight the modified phases and not to recombine them back with the initial phases so that any initial bias may be overcome. In the case of high noncrystallographic symmetry, it may also be possible to restore missing reflections in both amplitude and phase. Options are available for both these situations.

15.3.4.3. Phase-extension schemes

When performing phase extension, the order in which the structure factors are included will affect the final accuracy of the extended phases. The phases obtained from previous cycles of phase extension will be included in the calculation of new phases for the unphased structure factors in the next cycle. A reflection with more accurately determined phases might enhance the phase-extension power of the original set of reflections, whereas a reflection with less accurately determined phases might corrupt the phase-extension power of the original set of reflections and make the phase extension deteriorate quickly. The factors that might affect phase extension are the structure-factor amplitudes, the resolution shell and the figure of merit. Based on the above considerations, the following phase-extension schemes are provided in *DM*:

(1) Extension by resolution shell: This performs phase extension in resolution steps, starting from the low-resolution data, and extends the phase to the high-resolution limit of the data or that specified by the user. Structure factors are related by the reciprocal-space density-modification function that is dominated by low-resolution terms, as shown by equation (15.1.3.2) and Fig. 15.1.3.1 in Chapter 15.1. This means that only structure factors in a small region of reciprocal space are related. Thus, when initial phases are only available at low resolution, phase extension is performed by inclusion of successive resolution shells. In the case of fourfold or higher NCS, this can allow extension to 2 Å starting from initial phasing at 6 Å or worse.
(2) Extension in structure-factor amplitude steps: In this mode, those reflections with larger amplitudes are added first, gradually extending to those reflections with smaller amplitudes in many steps. The contribution of a reflection to the electron density is proportional to the square of its structure-factor amplitude according to Parseval's theorem, as shown in equation (15.3.5.1). This favours the protocol of extending the stronger reflections first so that they can be more reliably estimated. These stronger reflections will be used to phase relatively weaker subsequent reflections.
(3) Extension in figure-of-merit step: To extend phases for those structure factors with experimentally measured, albeit less accurate, phases and figures of merit, the reflections can be added in order of their figure of merit, starting from the highest to the lowest. It is advantageous to use the more reliably estimated phases with higher figure of merit to phase those reflections with lower figure of merit. This can be useful

when working with initial phasing from multiwavelength anomalous diffraction (MAD) or molecular replacement (MR) sources.

(4) Automatic mode: This combines the previous three extension schemes. The program automatically works out the optimum combination of the above three schemes according to the density-modification mode, the phase-combination mode and the nature of the input reflection data. The automatic mode is the default and is the recommended mode of choice unless specific circumstances warrant a different choice.

(5) All reflection mode: One advantage of the reflection-omit and perturbation-γ methods is that the strength of extrapolation of a structure-factor amplitude is a good indicator of the reliability of its corresponding phase. As a result, a phase-extension scheme is unnecessary in reflection-omit calculations; all reflections may be included from the first cycle.

15.3.5. Code description

The program was designed to be run largely automatically with minimal user intervention. This is achieved by using extensive default settings and by automatic selection of options based on the data used. The program is also modular by design so that additional density-modification methods can be incorporated easily.

A simplified flow diagram for *DM* is shown in Fig. 15.3.5.1(*a*). When a reflection-omit calculation is performed, an additional loop is introduced, shown in Fig. 15.3.5.1(*b*). The Sayre's equation calculation adds another level of complexity, described in Zhang & Main (1990*b*). Skeletonization imposes the protein histogram and solvent flatness implicitly and so is performed, if necessary, every second or third cycle in place of solvent flattening and histogram matching. Simplified conceptual and actual flow diagrams for *DMMULTI* are shown in Figs. 15.3.5.2(*a*) and (*b*).

Many of the basic approaches used in *DM* and *DMMULTI* are described in Chapter 15.1. Some practical aspects of the application and combination of these approaches are described here.

15.3.5.1. Scaling

All forms of map modification are affected by the overall temperature factor of the data, and histogram matching in particular is critically dependent on the accurate determination of the scale factor. Wilson statistics have been found inadequate for scaling in this case, especially when the data resolution is worse than 3 Å, because of the dip in scattering below 5 Å.

More accurate estimates of the scale and temperature factors may be achieved by fitting the data to a semi-empirical scattering curve (Cowtan & Main, 1998). This curve is prepared using Parseval's theorem, which relates the sum of the intensities to the variance of the map:

$$\sigma_\rho^2 = \frac{1}{V^2} \sum_{\mathbf{h}\neq 000} |F(\mathbf{h})|^2. \qquad (15.3.5.1)$$

Thus, the sum of the intensities in a particular resolution shell is proportional to the difference in variance of maps calculated with and without that shell of data. The empirical curve is therefore calculated from the variance in the protein regions of a group of known structures, calculated as a function of resolution. The curve is scaled to the protein volume of the current structure, and a correction is made for the solvent, which is assumed to be flat.

The overall temperature factor is removed, and an absolute scale is imposed by fitting the data to this curve. The use of sharpened F's (with no overall temperature factor) is necessary

for histogram matching and often increases the power of averaging for phase extension.

Since the solvent content is used in scaling the data, it is important that this value be entered correctly. However, the volume of the solvent mask may be varied independently of the true solvent content, as discussed in Section 15.3.3.

15.3.5.2. *Solvent-mask determination*

If the user does not supply a solvent mask, the solvent mask is calculated by Wang's (1985) method, using the reciprocal-space approach of Leslie (1987). A number of variants on this algorithm are implemented; however, the parameter that affects the quality of the solvent mask most dramatically is the radius of the smoothing function (Chapter 15.1). This parameter may be estimated empirically by

$$r_{\rm Wang} = 2r_{\max}\overline{w}^{1/3}, \qquad (15.3.5.2)$$

where $r_{\max}$ is the resolution limit of the observed amplitudes, and $\overline{w}$ is the mean figure of merit over the same reflections (with $w = 0$ for unphased reflections).

Once the smoothed map has been determined, cutoff values are chosen to divide the map into protein and solvent regions. If the protein boundary is poorly defined, the user may specify protein, solvent and excluded volumes, in which case two cutoffs are specified and the intermediate region is marked as neither protein nor solvent.

15.3.5.3. *Averaging-mask determination*

If the user does not supply an averaging mask, it is determined by a local correlation method (Vellieux *et al.*, 1995). A large region covering 27 unit cells is selected, and the local correlation between the maps before and after rotation by one of the noncrystallographic symmetry operators is calculated. The largest contiguous region that is in agreement among different NCS operators is isolated from the local correlation map, and a finer local correlation map is calculated over this volume. This process is iterated until a good mask with a detailed boundary is found.

This approach is fully automatic, except in the case where a noncrystallographic symmetry operator intersects a crystallographic symmetry operator, in which case the mask is not uniquely defined, and some user intervention may be required. The method is robust, and by increasing the radius of the sphere within which the local correlation is calculated, it may be used with very poor maps (Cowtan & Main, 1998). The method is easily extended to include information from multiple averaging operators.

15.3.5.4. *Fourier transforms*

For simplicity of coding, all Fourier transforms are performed in core using real-to-Hermitian and Hermitian-to-real fast Fourier transforms (FFTs). The data are expanded to space group *P*1 before calculating a map and averaged back to a reciprocal asymmetric unit after inverse transformation. Most of the map modifications preserve crystallographic symmetry, so restricted phases are not constrained except during phase combination.

15.3.5.5. *Histogram matching*

The target histograms are calculated from the protein regions of several stationary-atom structures at resolutions from 6 to 1.5 Å, according to the method described by Zhang & Main (1990*a*). The histogram variances should be consistent with the map variances used in scaling the data. The resolution of the target histogram can be accurately matched to the data resolution by averaging the target histograms on either side of the current resolution.

15.3.5.6. *Averaging*

Averaging is performed using a single-step approach (Rossmann *et al.*, 1992), in which every copy of the molecule in a 'virtual' asymmetric unit is averaged with every other copy. Density values are obtained at non-grid positions using a 27-point quadratic spectral spline interpolation. A sharpened map is first calculated by dividing by the Fourier transform of the quadratic spline function. The same spline function is then convoluted with the sharpened map to obtain the density value at an arbitrary coordinate (Cowtan & Main, 1998). This approach gives very accurate interpolation from a coarse grid map with relatively little computation and additionally provides gradient information for the refinement of averaging operators.

15.3.5.7. Multi-crystal averaging

The multi-crystal averaging calculation in *DMMULTI* is equivalent to several single-crystal averaging calculations running simultaneously, with the exception that during the averaging step, the molecule density is averaged across every copy in every crystal form. This average is weighted by the mean figure of merit of each crystal form; this allows the inclusion of unphased crystal forms, since in the first cycle they will have zero weight and therefore not disrupt the phasing that is already present. In subsequent cycles, the unphased form contains phase information from the back-transformed density.

This technique can be extremely useful, since adding a new crystal form usually provides considerably more phase information than adding a new derivative if the cross-rotation and translation functions can be solved.

In the multi-crystal case, averaging is performed using a two-step approach, first building an averaged molecule from all the copies in all crystal forms, then replacing the density in each crystal form with the averaged values. This approach is computationally more efficient when there are many copies of the molecule.

The conceptual flow chart of simultaneous density-modification calculations across multiple crystal forms is shown in Fig. 15.3.5.2(*a*); in practice, this scheme is implemented using a single process and looping over every crystal form at each stage (Fig. 15.3.5.2*b*). Maps are reconstructed from a large data object containing all the reflection data in every crystal form. Averaging is performed using a second data object containing maps of each averaging domain. By this means, an arbitrary number of domains may be averaged across an arbitrary number of crystal forms.

Multi-crystal averaging has been particularly successful in solving structures from very weak initial phasing, since the data redundancy is usually higher than for single-crystal problems.

PART 16. DIRECT METHODS

Chapter 16.1. *Ab initio* phasing

G. M. Sheldrick, C. J. Gilmore, H. A. Hauptman, C. M. Weeks, R. Miller and I. Usón

16.1.1. Introduction

Ab initio methods for solving the crystallographic phase problem rely on diffraction amplitudes alone and do not require prior knowledge of any atomic positions. General features that are not specific to the structure in question (*e.g.* the presence of α-helices, disulfide bridges or solvent regions) can, however, be utilized. For the last four decades, most small-molecule structures have been routinely solved by *direct methods*, a class of *ab initio* methods in which probabilistic phase relations are used to derive reflection phases from the measured amplitudes. The direct solution of new macromolecular structures in this way has, however, been limited to a few special cases involving relatively small macromolecules, unusually high-resolution data and, often, the presence of heavier atoms [which might also have been suitable for single-wavelength anomalous diffraction (SAD) or multiple-wavelength anomalous diffraction (MAD) phasing]. However, the same procedures can be applied at much lower resolution for the location of heavy-atom substructures, an essential step in the experimental phasing of macromolecules in the widely used SAD, single isomorphous replacement including anomalous scattering (SIRAS), multiple isomorphous replacement (MIR) and MAD methods. Indeed, substructure-based phasing now accounts for most direct-methods applications to macromolecules. Since three closely related dual-space direct methods computer programs (*SnB*, *SHELXD* and *HySS*) are currently used in the large majority of such applications, we will concentrate on this approach and then describe more briefly some other promising approaches, including one that does not require high-resolution data, a related molecule as search fragment or heavier atoms and should, therefore, be applicable to at least a quarter of the protein structures in the Protein Data Bank (PDB).

16.1.1.1. *Data resolution*

Direct methods of crystal structure determination have wholly transformed small-molecule crystallography in the past two decades. The same cannot be said for macromolecular crystallography, although there have been very significant advances in the area of substructure determination. The reasons for the success with small molecules are:

(1) automatic and easy to use software is readily and freely available [*e.g.* *SHELXS* and *SHELXD* (Sheldrick, 1990, 2008; Usón & Sheldrick, 1999), *SnB* (Miller *et al.*, 1994; Weeks & Miller, 1999*a*), *SIR2004* (Burla *et al.*, 2005), and *SUPERFLIP* (Palatinus & Chapuis, 2007)];

(2) the high quality and, in particular, high resolution of data now collected from both laboratory sources and synchrotron facilities; and

(3) data sets are complete with few missing reflections.

Why do data resolution and data quality matter? To understand this, we need to examine a rule proposed by Sheldrick (1990): *Experience with a large number of structures has led us to formulate the empirical rule that, if fewer than half the number of theoretically measurable reflections in the range 1.1 to 1.2 Å are 'observed' [i.e. have $F > 4\sigma(F)$], it is very unlikely that the structure can be solved by direct methods. This critical ratio may be reduced somewhat for centrosymmetric structures and structures containing heavy atoms.*

Morris and Bricogne (2003) offer valuable structural insights into this rule that are instructive for this chapter. By examining the averaged squared normalized structure-factor amplitudes of more than 700 high-resolution (<2.0 Å) structures as a function of data resolution, they found that there is always a pronounced maximum around 1.1 Å, a smaller one around 2.1 Å, and a further pronounced one at ~4.5 Å as shown in Fig. 16.1.1.1. The shape of these curves can be related back to a sinc function transformation which links the intensities of normalized structure-factor profiles and the radial pair distribution function. The peak at 1.1 Å can be shown to arise from bonded distances of ~1.5 Å and non-bonded distances of ~2.4 Å; every protein can be shown to contain distance beats of 1.1 Å arising from these. The net result is a systematic reduction in the expectation value of $|E|^2$ to about 1.25 Å and only then does it rise again. At 1.1–1.2 Å, the resolution is sufficient to reproduce a radial distance distribution with suitably separated peaks, and this gives not only atomicity, but also the stereochemical regularities necessary for the successful application of direct methods. To exacerbate matters further, the fundamental equations of direct methods have variances with a $1/N^{1/2}$ dependence, where N is the number of atoms in the unit cell. Morris and Bricogne make the matter clear: direct methods in their current formulation will always struggle with macromolecular data. This said, however, there are two significant and general uses of direct methods in macromolecular crystallography:

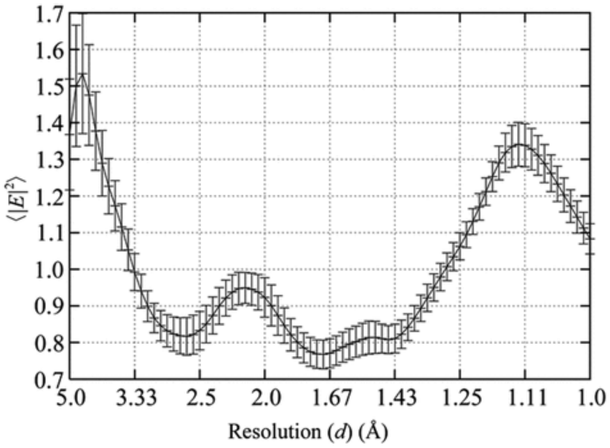

Figure 16.1.1.1
Averaged squared normalized structure-factor amplitudes over 700 protein structures with standard deviations calculated from the population of individual $|E|^2$ profiles (from Morris & Bricogne, 2003).

Figure 16.1.1.2
(*a*) Mean phase error as a function of resolution for the two independent *ab initio SHELXD* solutions of the previously unsolved protein hirustasin. Either the 1.2 Å or the 1.4 Å native data set led to solution of the structure. (*b*) Part of the hirustasin molecule from the 1.4 Å room-temperature data after one round of *B*-value refinement with fixed coordinates.

(1) *Ab initio* structure solution with atomic resolution data: the whole crystal structure solution is required with most of the atomic sites sufficiently defined for least-squares refinement. Sheldrick's rule applies rigorously here with very few exceptions in the literature. There have been isolated successes at lower resolutions, but these mostly involved the presence of heavier atoms or data with truncated resolution from crystals that would have diffracted further.

(2) Substructure solution: the determination of the positions of the heavy atoms only (often Se from selenomethionine, but also quite frequently heavy-atom salts, complexes and clusters). Sheldrick's rule is substantially relaxed and structure solutions at data resolutions of 5–6 Å are possible. This follows from the arguments of Morris and Bricogne: the distance beats of 1.1 Å are irrelevant to the substructure. By focusing on the heavy atoms, the complexity of the structure is much reduced, the distance between atoms is larger and the solution of the phase problem becomes easier.

The importance of the presence of several atoms heavier than oxygen for increasing the chance of obtaining a solution by the program *SnB* at resolutions less than 1.2 Å was noticed for truncated data from vancomycin and the 289-atom structure of conotoxin EpI (Weeks & Miller, 1999*b*). The results of *SHELXD* application to hirustasin, which contains ten sulfur and 457 carbon, nitrogen and oxygen atoms in the asymmetric unit, are consistent with this (Usón *et al.*, 1999). The 55-amino-acid protein hirustasin could be solved by *SHELXD* using either 1.2 Å low-temperature data or 1.4 Å room-temperature data. However, as shown in Fig. 16.1.1.2(*a*), the mean phase error (MPE) is significantly better for the 1.2 Å data over the whole resolution range. Although small-molecule interpretation based on peak positions worked well for the 1.2 Å solution (overall MPE $= 18°$), standard protein chain tracing was required for the 1.4 Å solution (overall MPE $= 26°$). As is clear from the corresponding electron-density map (Fig. 16.1.1.2*b*), *SHELXD* produced easily interpreted protein density even when bonded atoms are barely resolved from each other.

16.1.1.2. Data completeness

The relative effects of accuracy, completeness and resolution on *Shake-and-Bake* success rates using *SnB* for three large *P*1 structures were studied by computing error-free data using the known atomic coordinates (Xu *et al.*, 2000). The results of these studies, presented in Table 16.1.1.1, show that experimental error contributed nothing of consequence to the low success rates for vancomycin and lysozyme. However, completing the vancomycin data up to the maximum measured resolution of 0.97 Å resulted in a substantial increase in success rate which was further improved to an astounding success rate of 80% when the data were expanded to 0.85 Å. As a result of problems with overloaded reflections, the experimental vancomycin data did not include any data at 10 Å resolution or lower. A total of 4000 reflections were phased in the process of solving this structure with the experimental data. Some of these data were then replaced with the largest error-free magnitudes chosen from the missing reflections at several different resolution limits. The results in Table 16.1.1.2 show a tenfold increase in success rate when only 200 of the largest missing magnitudes were supplied, and it made no difference whether these reflections had a maximum resolution of 2.8 Å or were chosen randomly from the whole 0.97 Å sphere. The moral of this story is that, *when collecting synchrotron data for direct methods, it pays to take a second pass using a shorter exposure time to fill in the low-resolution data*.

16.1.1.3. Summary

The basic theory underlying direct methods has been summarized in an excellent chapter (Giacovazzo, 2008) in *International Tables for Crystallography* Volume B (Chapter 2.2) to which the reader is referred for details. Suffice it for this chapter to say that classical direct methods attempt to reconstruct the missing phase information using native data alone by utilizing direct relationships between the crystallographic phases without any *a priori* structural information.

From a historical perspective, the first successful applications of direct methods to native data for structures that could legiti-

Table 16.1.1.1

Table 16.1.1.2
Improving success rates by 'completing' the vancomycin data

Error-free reflections added	Success rate (%)
0	0.25
100 (3.5 Å)	0.3
200 (2.8 Å)	2.1
200 (0.97 Å)	2.4
400 (1.3 Å)	8.2
800 (1.1 Å)	11.1

mately be regarded as small macromolecules came from the *Shake-and-Bake* method and the associated *SnB* software (Weeks *et al.*, 1993). The distinctive feature of this procedure is the repeated and unconditional alternation of reciprocal-space phase refinement ('shaking') with a complementary real-space process that seeks to improve phases by applying constraints ('baking'). The first previously unknown structures determined by *Shake-and-Bake* were two forms of the 100-atom peptide ternatin (Miller *et al.*, 1993) and, so far, the largest previously unsolved structure solved by direct methods with no atom heavier than oxygen is probably feglymycin, with 1026 unique non-hydrogen atoms and data to 1.10 Å resolution (Bunkóczi *et al.*, 2005).

Using direct methods and accurately measured data, it is now possible to solve heavy-atom substructures of well over 100 atoms. For a state-of-the-art example, see von Delft *et al.* (2003), where a substructure of 160 Se atoms was solved in the product-bound *E. coli* KPHMT using *SnB*. A total of 120 sites were correctly located, allowing the remainder to be located by *SHARP* (de La Fortelle & Bricogne, 1997); in later tests, *SHELXD* was able to find 152 of the sites. For a review of the phase problem in the context of other developments, the reader is referred to a general overview by Dauter (2006).

The present chapter focuses on those aspects of direct methods that have proven useful for larger molecules (more than 250 independent non-H atoms) or are unique to the macromolecular field. These include direct-methods applications that utilize anomalous-dispersion measurements or multiple diffraction patterns [*i.e.* single isomorphous replacement (SIR), SAD and MAD] to locate substructures at resolutions typically in the range 2.0–3.5 Å, although lower-resolution data are sometimes adequate. A formal integration of the probabilistic machinery of direct methods with isomorphous replacement and anomalous dispersion was initiated in 1982 (Hauptman, 1982*a*,*b*). Although practical applications of this and subsequent related theory have been limited so far, this approach might prove relevant in the future. Similarly, the combination of direct methods with multiple-beam diffraction might also play a role (Weckert *et al.*, 1993).

Table 16.1.2.1
Theoretical values pertaining to $|E|$'s

	Centrosymmetric	Noncentrosymmetric
Average $\lvert E\rvert^2$	1.000	1.000
Average $\lvert \lvert E^2\rvert - 1\rvert$	0.968	0.736
Average $\lvert E\rvert$	0.798	0.886
$\lvert E\rvert > 1$ (%)	32.0	36.8
$\lvert E\rvert > 2$ (%)	5.0	1.8
$\lvert E\rvert > 3$ (%)	0.3	0.01

16.1.2. Normalized structure-factor magnitudes

For purposes of direct-methods computations, the usual structure factors, $F_{\mathbf{H}}$, are replaced by the *normalized structure factors* (Hauptman & Karle, 1953),

$$E_{\mathbf{H}} = |E_{\mathbf{H}}| \exp(i\varphi_{\mathbf{H}}),$$

$$|E_{\mathbf{H}}| = \frac{|F_{\mathbf{H}}|}{\langle |F_{\mathbf{H}}|^2 \rangle^{1/2}} = \frac{k\langle \exp[-B_{\rm iso}(\sin\theta)^2/\lambda^2] \rangle^{-1} |F_{\mathbf{H}}|_{\rm meas}}{\left(\varepsilon_{\mathbf{H}} \sum_{j=1}^{N} f_j^2\right)^{1/2}}, \qquad (16.1.2.1)$$

where the angle brackets indicate probabilistic or statistical expectation values, the $|E_{\mathbf{H}}|$ and $|F_{\mathbf{H}}|$ are structure-factor magnitudes, the $\varphi_{\mathbf{H}}$ are the corresponding phases, k is the absolute scaling factor for the measured magnitudes, $B_{\rm iso}$ is an overall isotropic atomic mean-square displacement parameter, the f_j are the atomic scattering factors for the N atoms in the unit cell, and the $\varepsilon_{\mathbf{H}} \geq 1$ are factors that account for multiple enhancement of the average intensities for certain special reflection classes due to space-group symmetry (Shmueli & Wilson, 2008). The condition $\langle |E|^2 \rangle = 1$ is always imposed. Unlike $\langle |F_{\mathbf{H}}| \rangle$, which decreases as $\sin(\theta)/\lambda$ increases, the values of $\langle |E_{\mathbf{H}}| \rangle$ are constant for concentric resolution shells. Thus, the normalization process places all reflections on a common basis, and this is a great advantage with regard to the probability distributions that form the foundation for direct methods. Normalizing a set of reflections by means of equation (16.1.2.1) does not require any information about atomic positions. However, if some structural information, such as the configuration, orientation, or position of certain atomic groupings, is available, then this information can be applied to obtain a better model for the expected intensity distribution (Main, 1976). The distribution of values is, in principle and often in practice, independent of the unit-cell size and contents, but it does depend on whether a centre of symmetry is present, as shown in Table 16.1.2.1.

Direct-methods applications having the objective of locating SIR or SAD substructures require the computation of normalized *difference* structure-factor magnitudes, $|E_\Delta|$. This can, for example, be accomplished with the following series of programs from Blessing's data-reduction and error-analysis routines (*DREAR*): *LEVY* and *EVAL* for structure-factor normalization as specified by equation (16.1.2.1) (Blessing *et al.*, 1996), *LOCSCL* for local scaling of the SIR and SAD magnitudes (Matthews & Czerwinski, 1975; Blessing, 1997), and *DIFFE* for computing the actual difference magnitudes (Blessing & Smith, 1999). The *SnB* program (see Section 16.1.12.4) provides a convenient interface to the *DREAR* suite.

16.1.2.1. SIR differences

Given the individual normalized structure-factor magnitudes for native structures ($|E_{\rm nat}|$) and for structures containing heavy atoms ($|E_{\rm der}|$), as well as the atomic scattering factors $|f_j| = |f_j^0 + f_j' + if_j''| = [(f_j^0 + f_j')^2 + (f_j'')^2]^{1/2}$ which allow for the possibility of anomalous scattering, then greatest-lower-bound estimates of SIR difference-E magnitudes are

$$|E_\Delta| = \frac{\left|\left(\sum_{j=1}^{N_{\rm der}} |f_j|^2\right)^{1/2} |E_{\rm der}| - \left(\sum_{j=1}^{N_{\rm nat}} |f_j|^2\right)^{1/2} |E_{\rm nat}|\right|}{q\left[\left(\sum_{j=1}^{N_{\rm der}} |f_j|^2\right) - \left(\sum_{j=1}^{N_{\rm nat}} |f_j|^2\right)\right]^{1/2}}, \quad (16.1.2.2)$$

where $q = q_0 \exp(q_1 s^2 + q_2 s^4)$ is a least-squares-fitted empirical renormalization scaling function, dependent on $\sin(\theta)/\lambda$, that imposes the condition $\langle |E_\Delta|^2 \rangle = 1$ and serves to define q_0, q_1 and q_2.

16.1.2.2. SAD differences

Given Friedel pairs of normalized structure-factor magnitudes ($|E_{+\mathbf{H}}|$, $|E_{-\mathbf{H}}|$) and the atomic scattering factors (f^0, f_j' and f_j''), then the greatest-lower-bound estimates of SAD difference $|E|$'s are

$$|E_\Delta| = \frac{\left[\sum_{j=1}^{N} (f_j^0 + f_j')^2 + (f_j'')^2\right]^{1/2} \big||E_{+\mathbf{H}}| - |E_{-\mathbf{H}}|\big|}{2q\left[\sum_{j=1}^{N} (f_j'')^2\right]^{1/2}}, \quad (16.1.2.3)$$

where, again, q is an empirical renormalization scaling function that imposes the condition $\langle |E_\Delta|^2 \rangle = 1$.

In the case of MAD data, the anomalous differences for all wavelengths can be combined in the form of F_A structure factors as described in Chapter 14.2 of this volume by Smith & Hendrickson. In the *SHELX* system, the program *SHELXC* prepares the $|F_A|$ values and the phase shifts α for SAD, SIR, SIRAS, RIP (radiation-damage-induced phasing) and MAD experimental phasing (Sheldrick, 2008, 2010), and the corresponding $|E_A|$ values are derived by *SHELXD*.

16.1.2.3. Difference intensities and direct methods

There are, of course, difficulties with normalized difference intensities. Direct methods normalize the data to give difference E magnitudes, and the macromolecular temperature factors incorporated in this process can be a source of error. The temperature-factor correction, often large for macromolecules, can take small, statistically dubious, amplitude differences at high resolution when working with anomalous difference data and magnify them into large normalized structure-factor differences that are then used in direct methods. These methods are very sensitive to such errors and will often fail unless a suitable resolution truncation limit is imposed. Usually this is around 0.5 Å larger than the experimental diffraction limit of the data or up to the resolution shell with $I/\sigma(I)$ = 10. Morris *et al.* (2004) have extended their work on profiles to devise a method of normalization based on $\langle |E|^2 \rangle$ profiles, and this should be more robust than traditional methods.

16.1.3. Starting the phasing process

The phase problem of X-ray crystallography may be defined as the problem of determining the phases φ of the normalized structure factors E when only the magnitudes $|E|$ are given. Owing to the atomicity of crystal structures and the redundancy of the known magnitudes, the phase problem is overdetermined and is, therefore, solvable in principle. This overdetermination implies the existence of relationships among the E's and, since the magnitudes $|E|$ are presumed to be known, there exist identities among the phases that are dependent on the known magnitudes alone. The techniques of probability theory lead to the joint probability distributions of arbitrary collections of E from which the conditional probability distributions of selected sets of phases, given the values of suitably chosen magnitudes $|E|$, may be inferred.

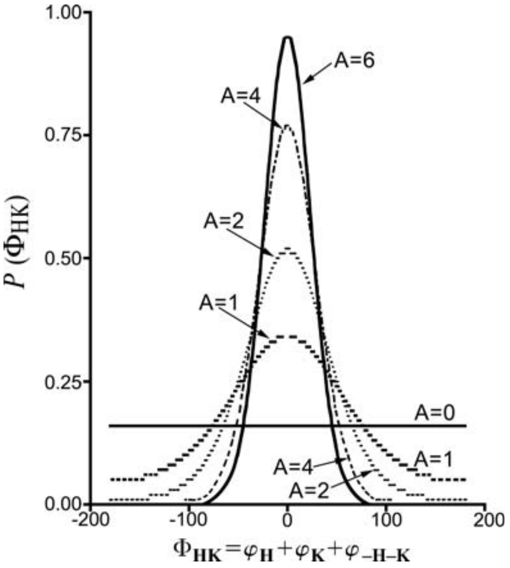

Figure 16.1.3.1

The conditional probability distribution, $P(\Phi_{\mathbf{HK}})$, of the three-phase structure invariants, $\Phi_{\mathbf{HK}}$, having associated parameters $A_{\mathbf{HK}}$ with values of 0, 1, 2, 4 and 6. When A $\simeq$ 0, all values of $\Phi_{\mathbf{HK}}$ are equally likely, and no information useful for phase determination is available. However, the sum of the three phases for most invariants with A $\simeq$ 6 is close to 0°, and an estimate of one phase can be made if the other two are known.

16.1.3.1. Structure invariants

The magnitude-dependent entities that constitute the foundation of direct methods are linear combinations of phases called *structure invariants*. The term 'structure invariant' stems from the fact that the values of these quantities are independent of the choice of origin. The most useful of the structure invariants are the three-phase or *triplet invariants*,

$$\Phi_{\mathbf{HK}} = \varphi_{\mathbf{H}} + \varphi_{\mathbf{K}} + \varphi_{-\mathbf{H}-\mathbf{K}}, \quad (16.1.3.1)$$

the conditional probability distribution (Cochran, 1955), given $A_{\mathbf{HK}}$, of which is

$$P(\Phi_{\mathbf{HK}}) = [2\pi I_0(A_{\mathbf{HK}})]^{-1} \exp(A_{\mathbf{HK}} \cos \Phi_{\mathbf{HK}}), \quad (16.1.3.2)$$

where

$$A_{\mathbf{HK}} = (2/N^{1/2})|E_{\mathbf{H}} E_{\mathbf{K}} E_{\mathbf{H}+\mathbf{K}}| \quad (16.1.3.3)$$

and N is the number of atoms, here presumed to be identical, in the primitive unit cell. This distribution is illustrated in Fig. 16.1.3.1. The expected value of the cosine of a particular triplet, $\Phi_{\mathbf{HK}}$, is given by the ratio of modified Bessel functions, $I_1(A_{\mathbf{HK}})/I_0(A_{\mathbf{HK}})$.

Estimates of the invariant values are most reliable when the normalized structure-factor magnitudes ($|E_{\mathbf{H}}|$, $|E_{\mathbf{K}}|$ and $|E_{-\mathbf{H}-\mathbf{K}}|$) are large and the number of atoms in the corresponding primitive unit cell, N, is small. This is one important reason why direct phasing is more difficult for macromolecules than it is for small molecules. Four-phase or quartet invariants have proven helpful in small-molecule structure determination, particularly when used passively as the basis for a figure of merit (DeTitta *et al.*, 1975). However, the reliability of these invariants, as given by their conditional probability distribution (Hauptman, 1975), is proportional to $1/N$, and they have not as yet been shown to be useful for macromolecular phasing. The reliability of higher-order invariants decreases even more rapidly as structure size increases.

16.1.3.2. *'Multisolution' methods and trial structures*

Successful crystal structure determination requires that sufficient phases be found such that a Fourier map computed using the corresponding structure factors will reveal the atomic positions. It is particularly important that the biggest terms (*i.e.*, largest $|E|$) be included in the Fourier series. Thus, the first step in the phasing process is to sort the reflections in decreasing order according to their $|E|$ values and to choose the number of large $|E|$ reflections that are to be phased. The second step is to generate the possible invariants involving these intense reflections and then to sort them in decreasing order according to their $A_{\mathbf{HK}}$ values. Those invariants with the largest $A_{\mathbf{HK}}$ values are retained in sufficient number to achieve the desired overdetermination. *Ab initio* phase determination by direct methods requires not only a set of invariants, the average values of the cosines of which are presumed to be known, but also a set of starting phases. Therefore, the third step in the phasing process is the assignment of initial phase values. If enough pairs of phases, $\varphi_{\mathbf{K}}$ and $\varphi_{-\mathbf{H}-\mathbf{K}}$, are known, the structure invariants can then be used to generate further phases ($\varphi_{\mathbf{H}}$) which, in turn, can be used to evaluate still more phases. Repeated iterations will permit most reflections with large $|E_{\mathbf{H}}|$ to be phased.

Depending on the space group, a small number of phases can be assigned arbitrarily in order to fix the origin position and, in noncentrosymmetric space groups, the enantiomorph or polar-axis direction. However, except for the simplest structures, these reflections provide an inadequate foundation for further phase development. Historically, a 'multisolution' or multi-trial approach (Germain & Woolfson, 1968) was taken in which other reflections are each assigned many different starting values in the hope that one or more of the resultant phase combinations will lead to a solution. Solutions, if they occurred, were identified on the basis of some suitable figure of merit. Although phases can be evaluated sequentially, the order determined by a so-called convergence map (Germain *et al.*, 1970), it has become standard in recent years to use a random-number generator to assign initial values to all available phases from the outset (Baggio *et al.*, 1978; Yao, 1981). A variant of this procedure is to use the random-number generator to assign initial coordinates to the atoms in the trial structures and then to obtain initial phases from a structure-factor calculation. In addition, some dual-space programs [*SHELXD* (Schneider & Sheldrick, 2002), *HySS* (Grosse-Kunstleve & Adams, 2003)] can also use the Patterson function to generate starting atoms or phases (see Section 16.1.8).

16.1.4. Reciprocal-space phase refinement or expansion (*shaking*)

Once a set of initial phases has been chosen, it must be refined against the set of structure invariants whose values are presumed known. In theory, any of a variety of optimization methods could be used to extract phase information in this way. However, so far only three purely reciprocal-space methods have been shown to be of practical value: tangent refinement, parameter-shift optimization of the minimal function, and maximization of Karle–Hauptman determinants (Section 16.1.12.7).

16.1.4.1. *The tangent formula*

The *tangent formula*,

$$\tan(\varphi_{\mathbf{H}}) = \frac{-\sum_{\mathbf{K}} |E_{\mathbf{K}}E_{-\mathbf{H}-\mathbf{K}}| \sin(\varphi_{\mathbf{K}} + \varphi_{-\mathbf{H}-\mathbf{K}})}{\sum_{\mathbf{K}} |E_{\mathbf{K}}E_{-\mathbf{H}-\mathbf{K}}| \cos(\varphi_{\mathbf{K}} + \varphi_{-\mathbf{H}-\mathbf{K}})}, \qquad (16.1.4.1)$$

(Karle & Hauptman, 1956), is the relationship used in conventional direct-methods programs to compute $\varphi_{\mathbf{H}}$ given a sufficient number of pairs $(\varphi_{\mathbf{K}}, \varphi_{-\mathbf{H}-\mathbf{K}})$ of known phases. It can also be used within the phase-refinement portion of the dual-space *Shake-and-Bake* procedure (Weeks, Hauptman *et al.*, 1994; Usón & Sheldrick, 1999). The variance associated with $\varphi_{\mathbf{H}}$ depends on $\sum_{\mathbf{K}} E_{\mathbf{H}}E_{\mathbf{K}}E_{-\mathbf{H}-\mathbf{K}}/N^{1/2}$ and, in practice, the estimate is only reliable for $|E_{\mathbf{H}}| \gg 1$ and for structures with a limited number of atoms (N). If equation (16.1.4.1) is used to redetermine previously known phases, the phasing process is referred to as *tangent-formula refinement*; if only new phases are determined, the phasing process is *tangent expansion*.

The tangent formula can be derived using the assumption of equal resolved atoms. Nevertheless, it suffers from the disadvantage that, in space groups without translational symmetry, it is perfectly fulfilled by a false solution with all phases equal to zero, thereby giving rise to the so-called 'uranium-atom' solution with one dominant peak in the corresponding Fourier synthesis. In conventional direct-methods programs, the tangent formula is often modified in various ways to include (explicitly or implicitly) information from the so-called 'negative' quartet invariants (Schenk, 1974; Hauptman, 1974; Giacovazzo, 1976) that are dependent on the smallest as well as the largest E magnitudes. Such modified tangent formulas do indeed largely overcome the problem of pseudosymmetric solutions for small N, but because of the dependence of quartet-term probabilities on $1/N$, they are little more effective than the normal tangent formula for large N.

16.1.4.2. *The minimal function*

Constrained minimization of an objective function like the *minimal function*,

$$R(\Phi) = \sum_{\mathbf{H},\mathbf{K}} A_{\mathbf{HK}}\big\{\cos\Phi_{\mathbf{HK}} - [I_1(A_{\mathbf{HK}})/I_0(A_{\mathbf{HK}})]\big\}^2 \Big/ \sum_{\mathbf{H},\mathbf{K}} A_{\mathbf{HK}} \qquad (16.1.4.2)$$

(Debaerdemaeker & Woolfson, 1983; Hauptman, 1991; DeTitta *et al.*, 1994), provides an alternative approach to phase refinement or phase expansion. $R(\Phi)$ is a measure of the mean-square difference between the values of the triplets calculated using a particular set of phases and the expected values of the same triplets as given by the ratio of modified Bessel functions. The minimal function is expected to have a constrained global minimum when the phases are equal to their correct values for some choice of origin and enantiomorph (the minimal principle). Experimentation has thus far confirmed that, when the minimal function is used actively in the phasing process and solutions are produced, the final trial structure corresponding to the smallest value of $R(\Phi)$ is a solution provided that $R(\Phi)$ is calculated directly from the atomic positions before the phase-refinement step (Weeks, DeTitta *et al.*, 1994). Therefore, $R(\Phi)$ is also an extremely useful figure of merit. The minimal function can also include contributions from higher-order (*e.g.* quartet) invariants, although their use is not as imperative as with the tangent formula because the minimal function does not have a minimum when all phases are zero. In practice, quartets are rarely used in the minimal function because they increase the CPU time while adding little useful information for large structures.

The cosine function in equation (16.1.4.2) can also be replaced by other functions of the phases giving rise to alternative minimal functions. Examples include an exponential expression that has been found to give superior results for several $P1$ structures (Hauptman *et al.*, 1999). In addition, substructure determination using a very simple and computationally efficient modified minimal function,

$$m(\varphi) = 1 - (N_I/N_T) \tag{16.1.4.3}$$

(where I is an arbitrary interval $[-r, r]$, N_I is the number of triplets whose values lie in I and N_T is the total number of triplets), has been reported (Xu & Hauptman, 2004, 2006; Xu *et al.*, 2005) and incorporated into the *BnP* software (see Section 16.1.12.4).

16.1.4.3. Parameter shift

In principle, any minimization technique could be used to minimize $R(\Phi)$ by varying the phases. So far, a seemingly simple algorithm, known as parameter shift (Bhuiya & Stanley, 1963), has proven to be quite powerful and efficient as an optimization method when used within the *Shake-and-Bake* context to reduce the value of the minimal function. For example, a typical phase-refinement stage consists of three iterations or scans through the reflection list, with each phase being shifted a maximum of two times by 90° in either the positive or negative direction during each iteration. The refined value for each phase is selected, in turn, through a process which involves evaluating the minimal function using the original phase and each of its shifted values (Weeks, DeTitta *et al.*, 1994). The phase value that results in the lowest minimal-function value is chosen at each step. Refined phases are used immediately in the subsequent refinement of other phases. It should be noted that the parameter-shift routine is similar to that used in ψ-map refinement (White & Woolfson, 1975) and *XMY* (Debaerdemaeker & Woolfson, 1989).

16.1.5. Real-space constraints (*baking*)

For several decades, classical direct methods operated exclusively in reciprocal space, determining phases through statistical relationships between them. Only when this process had converged did the method move into real space by calculating one or more electron-density maps that were examined using stereochemical criteria. In macromolecular crystallography, density modification has always played a central role in phasing. A major advance in direct methods for macromolecules (and large molecules in general) occurred when density-modification methods were incorporated and adapted into the phasing procedure. They are often very simple: peaks which give rise to unrealistic geometries or which are too weak are removed, new structure factors are calculated and hence new phase angles are derived in an iterative process. (They can also be quite sophisticated as in *ACORN2*, which we will discuss in Section 16.1.12.1.) A consequence of this is that the once-clear dividing line between direct methods and other structure-solution techniques has become somewhat blurred.

Peak picking is a simple but powerful way of imposing an atomicity constraint. The potential for real-space phase improvement in the context of small-molecule direct methods was recognized by Karle (1968). He found that even a relatively small, chemically sensible, fragment extracted by manual interpretation of an electron-density map could be expanded into a complete solution by transformation back to reciprocal space and then performing additional iterations of phase refinement with the tangent formula. Automatic real-space electron-density-map interpretation in the *Shake-and-Bake* procedure consists of selecting an appropriate number of the largest peaks in each cycle to be used as an updated trial structure without regard to chemical constraints other than a minimum allowed distance between atoms. If markedly unequal atoms are present, appropriate numbers of peaks (atoms) can be weighted by the proper atomic numbers during transformation back to reciprocal space in a subsequent structure-factor calculation. Thus, *a priori* knowledge concerning the chemical composition of the crystal is utilized, but no knowledge of constitution is required or used during peak selection. It is useful to think of peak picking in this context as simply an extreme form of density modification appropriate when atomic resolution data are available. In theory, under appropriate conditions it should be possible within the dual-space direct-methods framework to replace peak picking by alternative density-modification procedures such as low-density elimination (Shiono & Woolfson, 1992; Refaat & Woolfson, 1993) or solvent flattening (Wang, 1985). The imposition of physical constraints counteracts the tendency of phase refinement to propagate errors or produce overly consistent phase sets. Several variants of peak picking, which are discussed below, have been successfully employed within the framework of *Shake-and-Bake*.

16.1.5.1. Simple peak picking

In its simplest form, peak picking consists of simply selecting the top N_u E-map peaks where N_u is the number of unique non-H atoms in the asymmetric unit. This is adequate for true small-molecule structures. It has also been shown to work well for heavy-atom or anomalously scattering substructures where N_u is taken to be the number of expected substructure atoms (Smith *et al.*, 1998; Turner *et al.*, 1998). For larger structures ($N_u > 100$), it is likely to be better to select about $0.8N_u$ peaks, thereby taking into account the probable presence of some atoms that, owing to high thermal motion or disorder, will not be visible during the early stages of a structure determination. Furthermore, a study by Weeks & Miller (1999*b*) has shown that structures in the 250–1000-atom range which contain a half dozen or more moderately heavy atoms (*i.e.*, S, Cl, Fe) are more easily solved if only $0.4N_u$ peaks are selected. The only chemical information used at this stage is a minimum inter-peak distance, generally taken to be 1.0 Å. For substructure applications, a larger minimum distance (*e.g.* 3 Å) is more appropriate, provided that care is taken with disulfide bridges (Section 16.1.11).

16.1.5.2. Iterative peaklist optimization

An alternative approach to peak picking is to select approximately N_u peaks as potential atoms and then eliminate some of them, one by one, while maximizing a suitable figure of merit such as

$$P = \sum_{\mathbf{H}} |E_c^2|(|E_o^2| - 1). \tag{16.1.5.1}$$

The top N_u peaks are used as potential atoms to compute $|E_c|$. The atom that leaves the highest value of P is then eliminated. Typically, this procedure, which has been termed *iterative peaklist optimization* (Sheldrick & Gould, 1995), is repeated until only $2N_u/3$ atoms remain. Use of equation (16.1.5.1) may be regarded as a reciprocal-space method of maximizing the fit to the origin-removed sharpened Patterson function, and it has been used for this purpose in molecular replacement (Beurskens, 1981). Subject to various approximations, maximum-likelihood considerations also indicate that it is an appropriate function to maximize (Bricogne, 1998). Iterative peaklist optimization provides a higher percentage of solutions than simple peak picking, but it suffers from the disadvantage of requiring much more CPU time and so is less effective than the random-omit method described in the next section.

16.1.5.3. Random omit maps

A third peak-picking strategy involves selecting approximately $1.3N_u$ of the top peaks and eliminating some, but, in this case, the deleted peaks are chosen at random. Typically, one-third of the potential atoms are removed, and the remaining atoms are used to compute E_c. By analogy to the common practice in macromolecular crystallography of omitting part of a structure from a Fourier calculation in the hope of finding an improved position for the deleted fragment, this version of peak picking is described as *random omit*. This procedure helps to prevent the dual-space recycling from getting stuck in a local minimum and is thus an efficient search algorithm.

16.1.6. Fourier refinement

E-map recycling, but without phase refinement (Sheldrick, 1982, 1990; Kinneging & de Graaff, 1984), has been frequently used in conventional direct-methods programs to improve the completeness of the solutions after phase refinement. It is important to apply Fourier refinement to *Shake-and-Bake* solutions also because such processing significantly increases the number of resolved atoms, thereby making the job of map interpretation much easier. Since phase refinement *via* either the tangent formula or the minimal function requires relatively accurate invariants that can only be generated using the larger E magnitudes, a limited number of reflections are phased during the actual dual-space cycles. Working with a limited amount of data has the added advantage that less CPU time is required. However, if the current trial structure is the 'best' so far based on a figure of merit (either the minimal function or a real-space criterion), then it makes sense to subject this structure to Fourier refinement using additional data, thereby reducing series-termination errors. The correlation coefficient

$$\begin{aligned}\mathrm{CC} = {} & \left[\left(\sum wE_o^2E_c^2\sum w\right) - \left(\sum wE_o^2\sum wE_c^2\right)\right] \\ & \times \left\{\left[\left(\sum wE_o^4\sum w\right) - \left(\sum wE_o^2\right)^2\right]\right. \\ & \times \left.\left[\left(\sum wE_c^4\sum w\right) - \left(\sum wE_c^2\right)^2\right]\right\}^{-1/2} \qquad (16.1.6.1)\end{aligned}$$

(Fujinaga & Read, 1987), where weights $w = 1/[0.04 + \sigma^2(E_o)]$, has been found to be an especially effective figure of merit when used with all the data and is, therefore, suited for identifying the most promising trial structure at the end of Fourier refinement. Either simple peak picking or iterative peaklist optimization can be employed during the Fourier-refinement cycles in conjunction with weighted E maps (Sim, 1959). The final model can be further improved by isotropic displacement parameter ($B_{\rm iso}$) refinement for the individual atoms (Usón *et al.*, 1999) followed by calculation of the Sim (1959) or sigma-A (Read, 1986) weighted map. This is particularly useful when the requirement of atomic resolution is barely fulfilled, and it makes it easier to interpret the resulting maps by classical macromolecular methods.

16.1.7. Resolution enhancement: the 'free lunch' algorithm

Direct methods take a set of phases, refine them and also determine new ones. There is no reason, however, why they cannot be used to predict new amplitudes as well. If density modification of a real-space map is performed, then any process of real-space density modification will, following a Fourier transformation, give structure-factor amplitudes for reflections that were not used to generate it, and these can be outside the resolution limit. If direct methods require atomic resolution data, can we use these techniques to extrapolate structure factors (*i.e.* predict not only phases, but also amplitudes for missing data) and extend data resolution? The idea is not new, but it has been quite extensively studied in recent years. Sheldrick has termed such algorithms 'free lunch', with reference to the saying: 'There is no such thing as a free lunch'! In one example (Usón *et al.*, 2007), weak SIRAS starting phase information followed by density modification led to an $|F_o|$ weighted mean phase error (MPE) of 54° at 1.98 Å resolution, but when the density modification was performed with amplitude extrapolation to 1.0 Å, the MPE fell to 17°. Caliandro *et al.* (2005*a*,*b*) used Patterson or direct methods to obtain trial phases that are submitted to various density-modification methods. Following this, extrapolated phases were generated. This too transformed uninterpretable maps into a solution amenable to automatic tracing. Palatinus *et al.* (2007) used maximum entropy (ME) methods for amplitude extrapolation. In some ways these should be ideal for this purpose, and it is worth noting that ME maps have, *de facto*, optimal resolution enhancement built in, although they can be difficult to generate for large structures.

Why does this work, and why is it sometimes so spectacular? The answer probably lies with the fact that maps are much more sensitive to phases than amplitudes and, if the model bias of predicting new amplitudes is not too great, then using a nonzero value is better than zero, which is the default. Fourier-truncation errors may also be reduced, resulting in less spurious map detail.

16.1.8. Utilizing Pattersons for better starts

When slightly heavier atoms such as sulfur are present, it is possible to start recycling procedures from a set of atomic positions that are consistent with the Patterson function. For large structures, the vectors between such atoms will correspond to Patterson densities around or even below the noise level, so classical methods of locating the positions of these atoms unambiguously from the Patterson are unlikely to succeed. Nevertheless, the Patterson function can still be used to filter sets of starting atoms. This filter is currently implemented as follows in *SHELXD*. First, a sharpened Patterson function (Sheldrick *et al.*, 1993) is calculated, and the top 200 (for example) non-Harker peaks further than a given minimum distance from the origin are selected, in turn, as two-atom translation-search fragments, one such fragment being employed per solution attempt. For each of a large number of random translations, all unique Patterson vectors involving the two atoms and their symmetry equivalents are found and sorted in order of increasing Patterson density. The sum of the smallest third of these values is used as a figure of merit (PMF). Tests showed that although the globally highest PMF for a given two-atom search fragment may not correspond to correct atomic positions, nevertheless, by limiting the number of trials, some correct solutions may still be found. The two-atom vectors are chosen by biased random sampling that favours the vectors corresponding to higher Patterson values. The two atoms

Table 16.1.8.1
Overall success rates for full structure solution for hirustasin using different two-atom search vectors chosen from the Patterson peak list

Resolution (Å)	Two-atom search fragments	Solutions per 1000 attempts
1.2	Top 100 general Patterson peaks	86
1.2	Top 300 general Patterson peaks	38
1.2	One vector, error = 0.08 Å	14
1.2	One vector, error = 0.38 Å	41
1.2	One vector, error = 0.40 Å	219
1.2	One vector, error = 1.69 Å	51
1.4	Top 100 general Patterson peaks	10
1.5	Top 100 general Patterson peaks	4
1.5	One vector, error = 0.29 Å	61

may be used to generate further atoms using a full Patterson superposition minimum function or a weighted difference synthesis.

In the case of the small protein BPTI (Schneider, 1998), 15 300 attempts based on 100 different search vectors led to four final solutions with mean phase error less than 18°, although none of the globally highest PMF values for any of the search vectors corresponded to correct solutions. Table 16.1.8.1 shows the effect of using different two-atom search fragments for hirustasin, a previously unsolved 55-amino-acid protein containing five disulfide bridges first solved using *SHELXD* (Usón *et al.*, 1999). It is not clear why some search fragments perform so much better than others; surprisingly, one of the more effective search vectors deviates considerably (1.69 Å) from the nearest true S–S vector.

16.1.9. *Shake-and-Bake*: an analysis of a dual-space method in action

The *Shake-and-Bake* algorithm generated the *SnB* program written in Buffalo at the Hauptman–Woodward Institute, principally by Charles Weeks and Russ Miller (Miller *et al.*, 1994; Weeks & Miller, 1999*a*). *SHELXD* (Usón & Sheldrick, 1999; Schneider & Sheldrick, 2002) and later *HySS* (Grosse-Kunstleve & Adams, 2003) were both inspired by *SnB* and employ the *Shake-and-Bake* philosophy with various modifications, in particular involving the use of the Patterson function to obtain starting phases. It is instructive to see how such software works in detail.

16.1.9.1. Flowchart and program comparison

A flowchart for the generic *Shake-and-Bake* algorithm, which provides the foundation for these programs, is presented in Fig. 16.1.9.1. It contains two refinement loops embedded in the trial-structure loop. The first of these loops (steps 5–9) is a dual-space phase-improvement loop entered by all trial structures, and the second (steps 11–14) is a real-space Fourier-refinement loop entered only by those trial structures that are currently judged to be the best on the basis of some figure of merit. These loops have been called the internal and external loops, respectively, in previous descriptions of the *SHELXD* program (*e.g.* Sheldrick & Gould, 1995; Sheldrick, 1997, 1998). Currently, the major algorithmic differences between the programs are the following:

(*a*) During the reciprocal-space segment of the dual-space loop (Fig. 16.1.9.1, step 5), *SnB* can perform tangent refinement or use parameter shift to reduce the minimal function [equation (16.1.4.2)] or an exponential variant of the minimal function (Hauptman *et al.*, 1999). *SHELXD* performs Karle-type tangent expansion (Karle, 1968). During tangent or parameter-shift refinement with *SnB*, all phases computed in the preceding structure-factor calculation (steps 4 or 9) are refined. During tangent expansion in *SHELXD*, the phases of (typically) the 40% highest calculated E magnitudes are held fixed, and the phases of the remaining 60% are determined by using the tangent formula. If there is a tendency for *SHELXD* to produce uranium-atom solutions, more phases should be held fixed in the tangent phase expansion.

(*b*) In real space, *SnB* uses simple peak picking, varying the number of peaks selected on the basis of structure size and composition. *SHELXD* contains provisions for all the forms of peak picking described above.

(*c*) *SnB* relies primarily on the minimal function [equation (16.1.4.2)] as a figure of merit whereas *SHELXD* uses the correlation coefficient [equation (16.1.6.1)], calculated using all data, after the final dual-space (internal) cycle and in the real-space (external) loop. In addition, *SHELXD* calculates a further correlation coefficient, $\mathrm{CC}_{\mathrm{weak}}$, calculated in the same

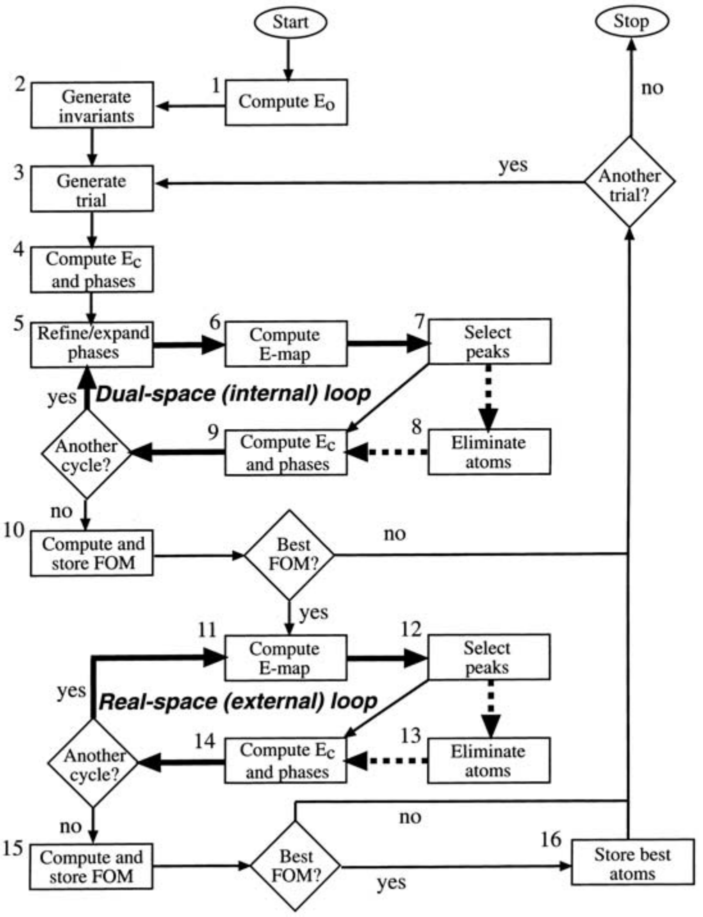

Figure 16.1.9.1
A flowchart for the *Shake-and-Bake* procedure, which is implemented in both *SnB* and *SHELXD*. The essence of the method is the dual-space approach of refining trial structures as they shuttle between real and reciprocal space. In the general case, steps 7 and 12 are any density-modification procedure, and steps 9 and 14 are inverse Fourier transforms rather than structure-factor calculations. The optional steps 8 and 13 take the form of *iterative peaklist optimization* or *random omit maps* in *SHELXD*. Any suitable starting model can be used in step 3, and *SHELXD* attempts to improve on random models (when possible) by utilizing Patterson-based information. Step 4 is bypassed if phase sets (random or otherwise) provide the starting point for the dual-space loop. *SHELXD* enters the real-space loop if the FOM (correlation coefficient) is within a specified threshold (1–5%) of the best value so far.

Table 16.1.9.1
Recommended parameter values for the *SnB* program

Values are expressed in terms of N_u, the number of unique non-H atoms (solvent atoms are typically ignored). Full-structure recommendations are for data sets measured to 1.1 Å resolution or better. Only heavy atoms or anomalous scatterers are counted for substructures.

Parameter	Full structures	Substructures
Phases	$10N_u$	$30N_u$
Triplet invariants	$100N_u$	$300N_u$
Peaks (with S, Cl) Peaks (no 'heavy')	$0.4N_u$ $0.8N_u$	N_u
Cycles	$N_u/2$ if $N_u < 100$ or if $N_u < 400$ with S, Cl *etc.*; N_u otherwise	$2N_u$ (minimum 20)

way but using only the weak reflections, *i.e.* those not used directly for phasing.

16.1.9.2. *Parameters and procedures*

All of the major parameters of the *Shake-and-Bake* procedure (*i.e.*, the numbers of refinement cycles, phases, triplet invariant relationships and peaks selected) are a function of structure size and can be expressed in terms of N_u, the number of unique non-H atoms in the asymmetric unit. These parameters have been fine-tuned in a series of tests using data for both small and large molecules (Weeks, DeTitta *et al.*, 1994; Chang *et al.*, 1997; Weeks & Miller, 1999*b*). Default (recommended) parameter values used in the *SnB* program are summarized in Table 16.1.9.1. At resolutions in the 1.1–1.4 Å range, recalcitrant data sets can sometimes be made to yield solutions if (1) the phase:invariant ratio is increased from 1:10 to values ranging between 1:20 and 1:50 or (2) the number of dual-space refinement cycles is doubled or tripled. The presence of moderately heavy atoms (*e.g.* S, C, Fe) greatly increases the probability of success at resolutions less than 1.2 Å; in general, the higher the fraction of such atoms the more the resolution requirement can be relaxed, provided that these atoms have low *B* values. Thus, disulfide bridges are much more helpful than methionine sulfur atoms because they tend to have lower *B* values. Parameter recommendations for substructures are based on an analysis of the peak-wavelength anomalous-difference data for S-adenosylhomocysteine (AdoHcy) hydrolase (Turner *et al.*, 1998). Parameter shift with a maximum of two 90° steps [indicated by the shorthand notation PS(90°, 2)] is the default phase-refinement mode. However, some structures (especially large *P*1 structures) may respond better to a single larger shift [*e.g.* PS(157.5°, 1)] (Deacon *et al.*, 1998). This seems to reduce the frequency of false minima (see Section 16.1.10.1).

In general, the parameter values used in *SHELXD* are similar to those used in *SnB*. However, the *combination* of random omit maps with tangent extension has been found to be the most effective strategy within the context of *SHELXD* for *ab initio* solution of the full stucture, and so is used as the default mode (see Section 16.1.10.2 for details). For substructure solution, especially for small substructures, it is normally faster to use starting atoms from Patterson seeding. Although both random omit and Patterson seeding can increase the success rate by an order of magnitude, combining both does not produce much further improvement. For very large substructures, and especially for very high symmetry space groups where the Patterson analysis is more time consuming, the random-omit procedure can be the more effective of the two. The largest substructure solved by *SHELXD* is probably PDB code 2pnk (to be published), solved by Qingping Xu of the Joint Center for Structural Genomics (JCSG), with 197 correct and no incorrect Se sites out of 205 (the other eight were disordered). About 1.6 million trials were needed (using multiple CPUs) to obtain one correct solution when Patterson seeding was employed, but with the random-omit method many good solutions were obtained. This example also illustrates the point that it is important not to give up too soon!

The substructure solution program *HySS* in the *PHENIX* system is more-or-less a clone of *SHELXD*. For further details see Section 16.1.12.5.

16.1.9.3. *Recognizing solutions*

On account of the intensive nature of the computations involved, *SnB* and *SHELXD* are designed to run unattended for long periods while also providing ways for the user to check the status of jobs in progress. The progress of current *SnB* jobs can be followed by monitoring a figure-of-merit histogram for the trial structures that have been processed (Fig. 16.1.9.2). A clear bimodal distribution of figure-of-merit values is a strong indication that a solution has, in fact, been found. However, not all solutions are so obvious, and it sometimes pays to inspect the best trial even when the histogram is unimodal. The course of a typical solution as a function of *SnB* cycle is contrasted with that of a nonsolution in Fig. 16.1.9.3. Minimal-function values for a solution usually decrease abruptly over the course of just a few cycles, and a tool is provided within *SnB* that allows the user to visually inspect the trace of minimal-function values for the best trial completed so far. Fig. 16.1.9.3 shows that the abrupt decrease in minimal-function values corresponds to a simultaneous abrupt increase in the number of peaks close to true atomic positions. In

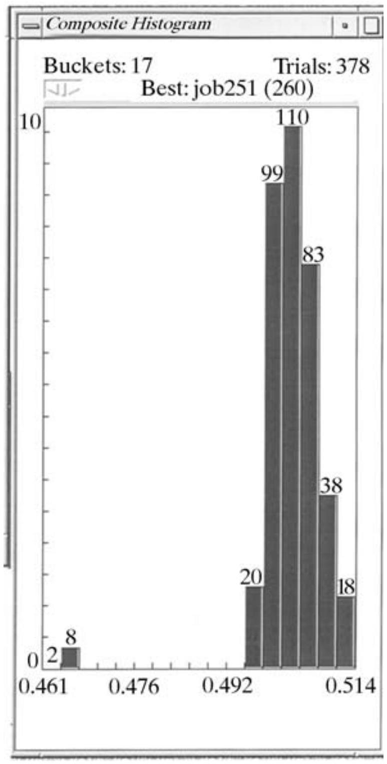

Figure 16.1.9.2
A histogram of figure-of-merit values (minimal function) for 378 scorpion toxin II trials. This bimodal histogram suggests that ten trials are solutions.

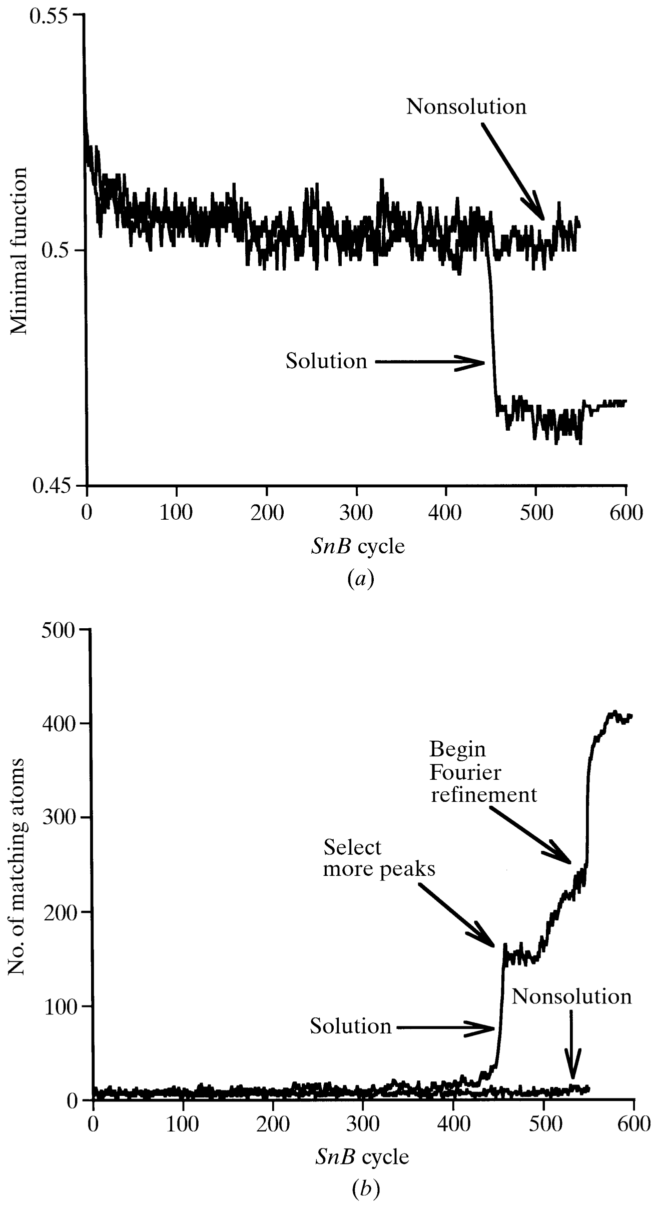

Figure 16.1.9.3

Tracing the history of a solution and a nonsolution trial for scorpion toxin II as a function *of Shake-and-Bake* cycle. (*a*) Minimal-function figure of merit, and (*b*) number of peaks closer than 0.5 Å to true atomic positions. Simple peak picking (200 or $0.4N_u$ peaks) was used for 500 (N_u) cycles, and 500 peaks (N_u) were then selected for an additional 50 ($0.1N_u$) dual-space cycles. The solution (which had the lowest minimal-function value) was then subjected to 50 cycles of Fourier refinement.

this example, a second abrupt increase in correct peaks occurs when Fourier refinement is started.

Since the correlation coefficient is a relatively absolute figure of merit (given atomic resolution, values greater than 65% almost invariably correspond to correct solutions), it is usually clear when *SHELXD* has solved a structure, although when the data do not extend to atomic resolution the CC values are less informative, and for a substructure they depend strongly on the data quality.

16.1.10. Applying dual-space programs successfully

The solution of the (known) structure of triclinic lysozyme by *SHELXD* and shortly afterwards by *SnB* (Deacon *et al.*, 1998) finally broke the 1000-atom barrier for direct methods (there happen to be 1001 protein atoms in this structure!). Both programs have also solved a large number of previously unsolved structures that had defeated conventional direct methods; some examples are listed in Table 16.1.10.1. The overall quality of solutions is generally very good, especially if appropriate action is taken during the Fourier-refinement stage. Most of the time, the *Shake-and-Bake* method works remarkably well, even for rather large structures. However, in problematic situations, the user needs to be aware of options that can increase the chance of success.

16.1.10.1. Avoiding false minima

The frequent imposition of real-space constraints appears to keep dual-space methods from producing most of the false minima that plague practitioners of conventional direct methods. Translated molecules have not been observed (so far), and traditionally problematic structures with polycyclic ring systems and long aliphatic chains are readily solved (McCourt *et al.*, 1996, 1997). False minima of the type that occur primarily in space groups lacking translational symmetry and are characterized by a single large 'uranium' peak do occur frequently in *P*1 and occasionally in other space groups. Triclinic hen egg-white lysozyme exhibits this phenomenon regardless of whether parameter-shift or tangent-formula phase refinement is employed. An example from another space group (*C*222) is provided by the Se substructure data for AdoHcy hydrolase (Turner *et al.*, 1998). In this case, many trials converge to false minima if the feature in the *SnB* program that eliminates peaks at special positions is not utilized.

The problem with false minima is most serious if they have a 'better' value of the figure of merit being used for diagnostic purposes than do the true solutions. Fortunately, this is not the case with the uranium 'solutions', which can be distinguished on the basis of the minimal function [equation (16.1.4.2)] or the correlation coefficient [equation (16.1.6.1)]. However, it would be inefficient to compute the latter in each dual-space cycle since it requires that essentially all reflections be used. To be an effective discriminator, the figure of merit must be computed using the phases calculated from the point-atom model, not from the phases directly after refinement. Phase refinement can and does produce sets of phases, such as the uranium phases, which do not correspond to physical reality. Hence, it should not be surprising that such phase sets might appear 'better' than the true phases and could lead to an erroneous choice for the best trial. Peak picking, followed by a structure-factor calculation in which the peaks are sensibly weighted, converts the phase set back to physically allowed values. If the value of the minimal function computed from the refined or *unconstrained* phases is denoted by $R_{\rm unc}$ and the value of the minimal function computed using the *constrained* phases resulting from the atomic model is denoted by $R_{\rm con}$, then a function defined by

$$R \text{ ratio} = (R_{\rm con} - R_{\rm unc})/(R_{\rm con} + R_{\rm unc}) \qquad (16.1.10.1)$$

can be used to distinguish false minima from other nonsolutions as well as the true solutions (Xu *et al.*, 2000). Once a trial falls into a false minimum, it never escapes. Therefore, the *R* ratio can be used, within *SnB*, as a criterion for early termination of unproductive trials. Based on data for several *P*1 structures, it appears that termination of trials with *R* ratio values exceeding 0.2 will eliminate most false minima without risking rejection of any potential solutions. In the case of triclinic lysozyme, false minima can be recognized, on average, by cycle 25. Since the default recommendation would be for 1000 cycles, a substantial saving in CPU time is realized by using the *R* ratio early-termination test.

Table 16.1.10.1
Some large structures solved by the *Shake-and-Bake* method

Previously known test data sets are indicated by an asterisk (*). When two numbers are given in the resolution column, the second indicates the lowest resolution at which truncated data have yielded a solution. The program codes are *SnB* (S) and *SHELXD* (D). The largest substructures solved by these two programs are mentioned in the text.

Compound	Space group	N_u (molecule)	N_u + solvent	N_u (heavy)	Resolution (Å)	Program	Reference

It should be noted that *SHELXD* optionally deletes the highest peak if the second peak is less than a specified fraction (*e.g.* 40%) of the height of the first, in an attempt to 'kick' the structure out of a false minimum.

Recognizing false minima is, of course, only part of the battle. It is also necessary to find a real solution, and essentially 100% of the triclinic lysozyme trials were found to be false minima when the standard parameter-shift conditions of two 90° shifts were used. In fact, significant numbers of solutions occur only when single-shift angles in the range 140–170° are used (Fig. 16.1.10.1), and there is a surprisingly high *success rate* (percentage of trial structures that go to solutions) over a narrow range of angles centred about 157.5°. It is also not surprising that there is a correlated decrease in the percentage of false minima in the range 140–150°. This suggests that a fruitful strategy for structures that exhibit a large percentage of false minima would be the following. Run 100 or so trials at each of several shift angles in the range 90–180°, find the smallest angle which gives nearly zero false minima, and then use this angle as a single shift for many trials. Balhimycin (Schäfer *et al.*, 1998) is an example of a large non-$P1$ structure that also requires a parameter shift of around 154° to obtain a solution using the minimal function.

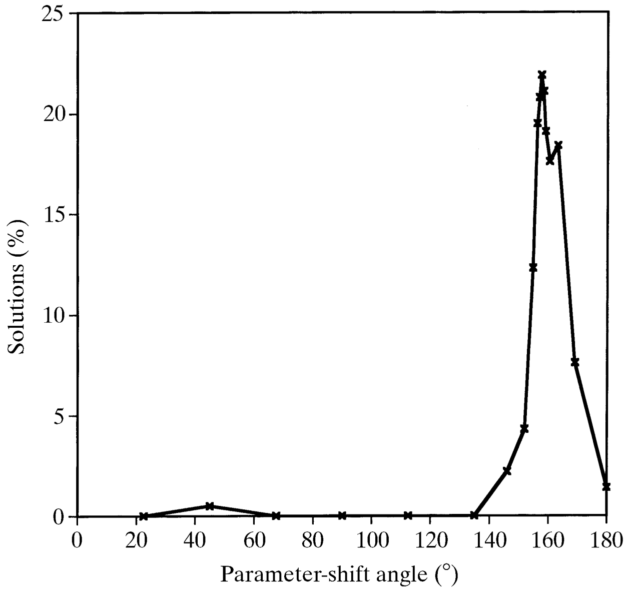

Figure 16.1.10.1
Success rates for triclinic lysozyme are strongly influenced by the size of the parameter-shift angle. Each point represents a minimum of 256 trials.

16.1.10.2. Choosing a refinement strategy

Variations in the computational details of the dual-space loop can make major differences in the efficacy of *SnB* and *SHELXD*. Fig. 16.1.10.2 shows the results of different strategies tested on a 148-atom $P1$ structure (Karle *et al.*, 1989) while developing *SHELXD*. The CPU time requirements of parameter-shift (PS) and tangent-formula expansion (TE) are similar, both being slower than no phase refinement (NR). In real space, the random-omit-map strategy (RO) was slightly faster than simple peak picking (PP) because fewer atoms were used in the structure-factor calculations. Both of these procedures were much faster than iterative peaklist optimization (PO). The original *SHELXD* algorithm (TE + PO) performs quite well in comparison with the *SnB* algorithm (PS + PP) in terms of the percentage of correct solutions, but less well when the efficiency is compared in terms of CPU time per solution. Surprising, the two strategies involving random omit maps (PS + RO and TE + RO), which had been included in the test as placebos, are much more effective than the other algorithms, especially in terms of CPU efficiency. Indeed these two runs appear to approach a 100% success rate as the number of cycles becomes large. The combination of random omit maps and Karle-type tangent

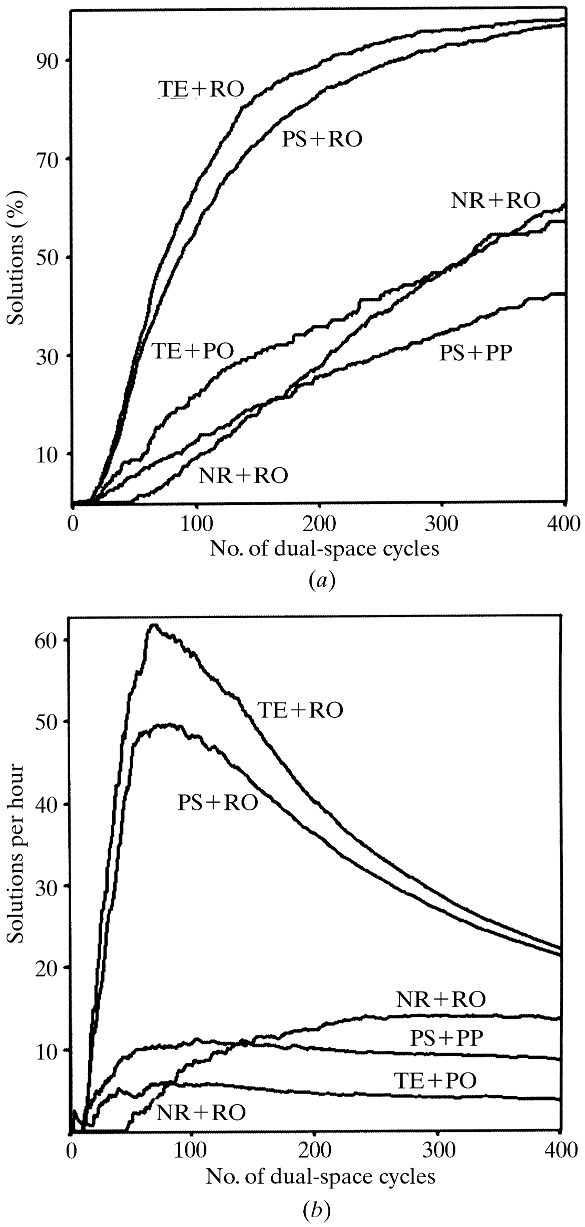

Figure 16.1.10.2

(*a*) Success rates and (*b*) cost effectiveness for several dual-space strategies as applied to a 148-atom $P1$ structure. The *phase-refinement strategies* are: (PS) parameter-shift reduction of the minimal-function value, (TE) Karle-type tangent expansion (holding the top 40% highest E_c fixed) and (NR) no phase refinement but Sim (1959) weights applied in the E map (these depend on E_c and so cannot be employed after phase refinement). The *real-space strategies* are: (PP) simple peak picking using $0.8N_u$ peaks, (PO) peaklist optimization (reducing N_u peaks to $2N_u/3$), and (RO) random omit maps (also reducing N_u peaks to $2N_u/3$). A total of about 10 000 trials of 400 internal loop cycles each were used to construct this diagram.

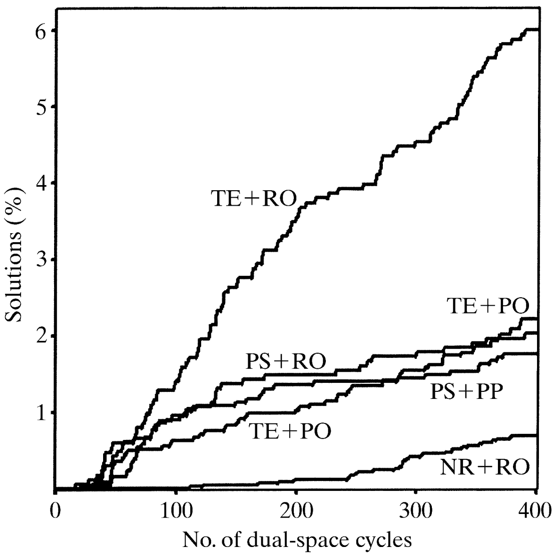

Figure 16.1.10.3

Success rates for the 317-atom $P2_12_12_1$ structure of gramicidin A.

expansion appears to be even more effective (Fig. 16.1.10.3) for gramicidin A, a $P2_12_12_1$ structure (Langs, 1988). It should be noted that conventional direct methods incorporating the tangent formula tend to perform better for this space group than in $P1$, perhaps because there is less risk of a uranium-atom pseudo-solution.

Subsequent tests using *SHELXD* on several other structures have shown that the use of random omit maps is much more effective than picking the same final number of peaks from the top of the peak list. However, it should be stressed that it is the combination TE + RO that is particularly effective. A possible special case is when a very small number of atoms is sought (*e.g.* Se atoms from MAD data). Preliminary tests indicate that peaklist optimization (PO) is competitive in such cases because the CPU time penalty associated with it is much smaller than when many atoms are involved.

With hindsight, it is possible to understand why the random omit maps provide such an efficient *search algorithm*. In macromolecular structure refinement, it is standard practice to omit parts of the model that do not fit the current electron density well, to perform some refinement or simulated annealing (Hodel *et al.*, 1992) on the rest of the model to reduce memory effects, and then to calculate a new weighted electron-density map (omit map). If the original features reappear in the new density, they were probably correct; in other cases the omit map may enable a new and better interpretation. Thus, random omit maps should not lead to the loss of an essentially correct solution, but enable efficient searching in other cases. It is also interesting to note that the results presented in Figs. 16.1.10.2 and 16.1.10.3 show that it is possible, albeit much less efficiently, to solve both structures using random omit maps without the use of any phase relationships based on probability theory (curves NR + RO).

16.1.10.3. Expansion to P1

The results shown in Table 16.1.1.1 and Fig. 16.1.10.2 indicate that success rates in space group $P1$ can be anomalously high. This suggests that it might be advantageous to expand all structures to $P1$ and then to locate the symmetry elements afterwards. However, this is more computationally expensive than performing the whole procedure in the true space group, and in practice such a strategy is only competitive in low-symmetry space groups such as $P2_1$, $C2$ or $P\bar{1}$ (Chang *et al.*, 1997). Expansion to $P1$ also offers some opportunities for starting from ‘slightly better than random’ phases. One possibility, successfully demonstrated by Sheldrick & Gould (1995), is to use a rotation search for a small fragment (*e.g.* a short piece of α-helix) to generate many sets of starting phases; after expansion to $P1$ the translational search usually required for molecular replacement is not needed. Various Patterson superposition minimum functions (Sheldrick & Gould, 1995; Pavelčík, 1994) can also provide an excellent start for phase determination for data expanded to $P1$. Drendel *et al.* (1995) were successful in solving small organic structures *ab initio* by a Fourier recycling method using perturbed Fourier amplitudes and data expanded to $P1$ without the use of probability theory. The random-omit procedure combined with expansion to $P1$ in *SHELXD* also enables structures to be solved efficiently even when the tangent formula phase extension is switched off; this has the advantage that lower E values can be used than would be suitable for the tangent formula, but at the cost of increasing the CPU time per solution. The program *ACORN2* (Dodson & Woolfson, 2009) is also particularly effective in $P1$; it applies sophisticated density modification and dual-space recycling with a special density disturbance term (POWDM) that is applied every tenth cycle. For the $P1$ form of lysozyme (see Table 16.1.10.1), good phases can be obtained by *ACORN2* starting from a fragment as small as two sulfur atoms for the 0.93 Å data. Expansion of the data to $P1$ is an essential feature of the charge-flipping approach described in Section 16.1.12.6. In general, one can say that dual-space recycling of data expanded to $P1$ requires some reasonable perturbation of the density (*e.g.* charge flipping or random peak omit) to prevent stagnation, but with this precaution provides a simple and effective approach to structure solution.

16.1.10.4. *Substructure applications*

It has been known for some time that conventional direct methods can be a valuable tool for locating the positions of heavy-atom substructures using isomorphous (Wilson, 1978) and anomalous (Mukherjee *et al.*, 1989) difference structure factors. Experience has shown that successful substructure applications are highly dependent on the accuracy of the difference magnitudes. As the technology for producing selenomethionine-substituted proteins and collecting accurate multiple-wavelength (MAD) data has improved (Hendrickson & Ogata, 1997; Smith, 1998), there has been an increased need to locate many selenium sites. For larger structures (*e.g.* more than about 30 Se atoms), automated Patterson interpretation methods can be expected to run into difficulties since the number of unique peaks to be analysed increases with the square of the number of atoms. Experimentally measured difference data are an approximation to the data for the hypothetical substructure, and it is reasonable to expect that conventional direct methods might run into difficulties sooner when applied to such data. Dual-space direct methods provide a more robust foundation for handling such data, which are often extremely noisy. Dual-space methods also have the added advantage that the expected number of Se atoms, N_u, which is usually known, can be exploited directly by picking the top N_u peaks. Successful applications require great care in data processing, especially if the $|F_A|$ values resulting from a MAD experiment are to be used.

SHELXD is frequently successfully employed with $|F_A|$ values derived from multiwavelength MAD data generated, for example, by the programs *SHELXC* (Sheldrick, 2008, 2010) or *XPREP* (Bruker AXS, Madison, WI). The decision at which resolution the data should be truncated for substructure determination is best taken on the basis of the correlation coefficients between the signed anomalous differences (Schneider & Sheldrick, 2002). On the other hand, *SnB* is normally applied separately to anomalous and dispersive differences. In many cases, both approaches lead to successful substructure solution. The real advantage of MAD data is that they provide more experimental phase information (*i.e.* better maps) and this is most important at medium to low resolution. The amount of data available for substructure problems is much larger than for full-structure problems with a comparable number of atoms to be located. Consequently, the user can afford to be stringent in eliminating data with uncertain measurements. Guidelines for rejecting uncertain data have been suggested (Smith *et al.*, 1998). Consideration should be limited to those data pairs $(|E_1|, |E_2|)$ [*i.e.*, isomorphous pairs $(|E_{\rm nat}|, |E_{\rm der}|)$ and anomalous pairs $(|E_{+\mathbf{H}}|, |E_{-\mathbf{H}}|)$] for which

$$\min\big[|E_1|/\sigma(|E_1|), |E_2|/\sigma(|E_2|)\big] \geq x_{\min} \qquad (16.1.10.2)$$

and

$$\frac{||E_1| - |E_2||}{[\sigma^2(|E_1|) + \sigma^2(|E_2|)]^{1/2}} \geq y_{\min}, \qquad (16.1.10.3)$$

where typically $x_{\min} = 3$ and $y_{\min} = 1$. The final choice of maximum resolution to be used should be based on inspection of the spherical shell averages $\langle|E_\Delta|^2\rangle_s$ *versus* $\langle s\rangle$ where $s = \sin(\theta)/\lambda$. The purpose of this precaution is to avoid spuriously large $|E_\Delta|$ values for high-resolution data pairs measured with large uncertainties due to imperfect isomorphism or general fall-off of scattering intensity with increasing scattering angle. Only those $|E_\Delta|$'s for which

$$|E_\Delta|/\sigma(|E_\Delta|) \geq z_{\min} \qquad (16.1.10.4)$$

(typically $z_{\min} = 3$) should be deemed sufficiently reliable for subsequent phasing. The probability of very large difference $|E|$'s (*e.g.* >5) is remote, and data sets that appear to have many such measurements should be examined critically for measurement errors. If a few such data remain even after the adoption of rigorous rejection criteria, it may be best to eliminate them individually. A paper by Blessing & Smith (1999) elaborates further data-selection criteria. On the other hand, it is also important that the phase:invariant ratio be maintained at 1:10 in order to ensure that the phases are overdetermined. Since the largest $|E|$'s for the substructure cell are more widely separated than they are in a true small-molecule cell, the relative number of possible triplets involving the largest reciprocal-lattice vectors may turn out to be too small. Consequently, a relatively small number of substructure phases (*e.g.* $10N_u$) may not have a sufficient number (*i.e.*, $100N_u$) of invariants. Since the number of triplets increases rapidly with the number of reflections considered, the appropriate action in such cases is to increase the number of reflections, as suggested in Table 16.1.9.1. This will typically produce the desired overdetermination.

It is rare for Se atoms to be closer to each other than 5 Å, and the application of *SnB* to AdoHcy hydolase data truncated to 4 and 5 Å has been successful. Success rates were less for lower-resolution data, but the CPU time required per trial was also reduced, primarily because much smaller Fourier grids were necessary. Consequently, there was no net increase in the CPU time needed to find a solution.

16.1.11. Substructure solution for native sulfurs and halide soaks

In the past, experimental phasing usually involved either the preparation of selenomethionine derivatives or the incorporation of heavy-metal ions by soaking crystals with a low concentration of the metal salt for several hours. The first of these methods required time in the wet lab and did not work well for all expression systems; the second had a low success rate. The improved quality of modern diffraction data collected from cryocooled crystals makes it now possible to exploit the weak anomalous signal from the native sulfur atoms or from halide ions introduced by soaking with a high concentration of a halide (iodide or bromide) for a few seconds immediately before cryocooling the crystal (Dauter *et al.*, 2000, 2001; Usón *et al.*,

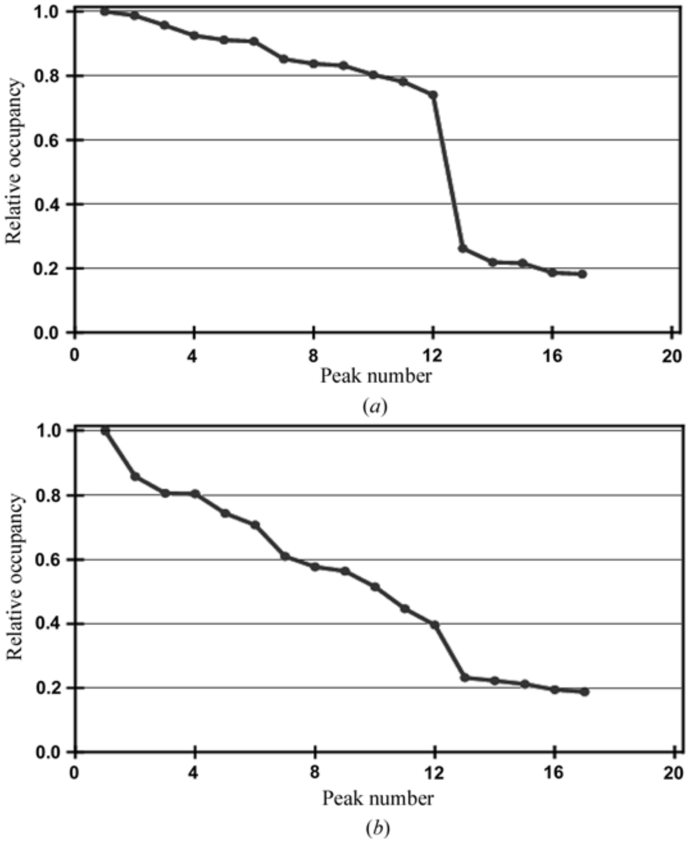

Figure 16.1.11.1

Relative occupancy against peak number for *SHELXD* substructure solutions of elastase. (*a*) Sulfur-SAD experiment showing the presence of the 12 expected sulfur atoms. (*b*) Iodide soak. Subsequent analysis showed that the peaks with relative occupancies less than 0.2 are mainly noise. These figures were made with *HKL2MAP* (Pape & Schneider, 2004).

2003). The success of these approaches is also made possible by the ability of modern, dual-space, substructure-solution programs to locate correctly a large number of sites, possibly with varying occupancies, using the SAD and SIRAS approaches.

In selenomethionine SAD and MAD phasing and in sulfur SAD phasing, the variation of the occupancies (refined in the final two cycles in the case of *SHELXD*) provides a very good indication as to whether the structure has been solved. Fig. 16.1.11.1(*a*) shows the phasing of elastase with sulfur SAD; a sharp drop in the relative occupancy after the 12th site confirms the expected presence of 12 sulfur atoms. For an iodide soak of the same protein (Fig. 16.1.11.1*b*), the relative occupancies show a gradual fall with peak number. Since the number of sites is difficult to estimate in advance for a halide soak and *SHELXD* needs to know this number approximately (within say 20%), it may be necessary to make several trials with different numbers of expected sites. From experience, the best number to use is the one that causes the occupancies to fall to about 0.2 relative to the strongest peak. Usually, subsequent refinements of the occupancies show that all the sites are partially occupied for halide soaks.

When the anomalous signal does not extend beyond about 2.0 Å, the two sulfur atoms of a disulfide bridge coalesce to a single maximum, often referred to as a supersulfur atom. At low resolution, this increases the signal-to-noise ratio for such sites in the dual-space procedure, but tends to impede phase extension to higher resolution (*e.g.* when density modification is applied to the native data with the starting phases estimated using these supersulfur atoms). An efficient way around this problem is to fit dumbbells rather than single atoms in the peak-search part of the dual-space recycling (Debreczeni *et al.*, 2003); this dramatically improves the quality of the higher-resolution starting phases.

Because the weak anomalous signal is swamped by the noise at higher resolution in such SAD experiments, it is often essential to truncate the resolution of the anomalous difference data before searching for the substructure. For MAD experiments, it is customary to truncate the data to the resolution at which the correlation coefficient between the signed anomalous differences falls below 30% (Schneider & Sheldrick, 2002). The same criterion can be used for SAD experiments if two independent data sets (*e.g.* from two different crystals) are available. As a compromise, the signed anomalous differences can be divided randomly into two sets, and then the correlation coefficient between them can be calculated. However, since these sets are not completely independent, a higher threshold (say 40%) might be advisable. An alternative criterion is to truncate the data at the point where the ratio of the mean absolute anomalous difference to its mean standard deviation falls below ~1.3, but this requires rather precise estimates of the standard deviations. In borderline cases, especially when multiple CPUs are available, it is probably safer simply to run the substructure solution for a range of different resolution cutoffs in parallel, and this is already implemented in several of the automated phasing pipelines. Sometimes good solutions are only obtained in a rather limited resolution cutoff range. A good starting value for sulfur SAD is the diffraction limit plus 0.5 Å.

16.1.12. Computer programs for dual-space phasing

Macromolecular crystallography is well served with free, high-quality, open-source software. Programs that provide direct-methods phasing for macromolecular problems will now be outlined. Although they all (except *CRUNCH2*) implement procedures that can be described more-or-less as dual-space methods, there are also appreciable differences from the three programs discussed so far. In this section, we have attempted to highlight these differences.

16.1.12.1. *ACORN*

ACORN (Yao *et al.*, 2006) and its successor *ACORN2* (Dodson & Woolfson, 2009) start with a fragment. This fragment can be very small: 1–8% in *ACORN*, and as little as 0.25% of the scattering is reported for *ACORN2*. Strictly speaking, these are not direct-methods programs, since they solve and refine crystal structures from poor starting phase sets that are usually derived from a known fragment. However, since this fragment can be very small, and since for $P1$ structures a single heavy atom at the origin suffices as a useable starting point, they are included here.

The data are normalized to give E magnitudes and partitioned into three sets: (1) large observed normalized magnitudes, (2) small magnitudes (typically < 0.2), and (3) the unobserved reflections (which are given values of unity) for a resolution range. A fragment is used to generate a set of phases, and this is followed by a sophisticated density-modification procedure:

$$\begin{aligned}
&\rho^{(n+1)} = 0 \quad \text{if} \quad \rho^{(n)} \le L\sigma,\\
&\rho^{(n+1)} = \rho^{(n)} \tanh[0.2(\rho^{(n)}/\sigma)^{\eta}] \quad \text{if} \quad \rho^{(n)} > L\sigma, \qquad (16.1.12.1)\\
&\rho^{(n+1)} = T\sigma \quad \text{if} \quad \rho^{(n+1)} > T\sigma,
\end{aligned}$$

where σ is the standard deviation of the map density and

$$T = \max(T_1 + c + 0.5c^2, 100),$$

$$T_1 = \left(\frac{M}{N}\right)^{1/2}\frac{Z_{\max}}{14}; \quad 3 \le T_1 \le 15, \qquad (16.1.12.2)$$

where M is the number of observable reflections within the resolution sphere and N is the number of atoms in the unit cell (excluding H atoms). The unconstrained value of T_1 is approximately 0.5 of the expected peak height of the heaviest atom in the E map with perfect phases; c is the cycle number.

$$L = L_1 - L_1^{c/n},$$

$$L_1 = 1.05\left[\left(B/r^2\right) - 1\right]\Phi(Z_{\max}), \qquad (16.1.12.3)$$

where B is the usual overall temperature factor; Φ is a cubic function going through the points (Φ, Z) = (0.84, 16), (0.96, 30), (1.15, 34.5) and (1.24, 48). If $Z_{\max} < 16$, the value $Z = 16$ (corresponding to sulfur) is used, and for $Z_{\max} > 48$, the value $Z = 48$ (corresponding to cadmium) is used. The value of L is thus reduced in n cycles from L_1 to zero.

$$n = \mathrm{nint}(0.5/p), \qquad (16.1.12.4)$$

where 'nint' indicates the nearest integer and

$$p = \frac{\sum_{\rm fragment} Z^2}{\sum_{\rm all\ atoms} Z^2}. \qquad (16.1.12.5)$$

Finally,

$$\eta = 17.24(r-1)^5 + 1.5. \qquad (16.1.12.6)$$

This use of η improves performance at low resolution. There is also an E limit,

$$E_{\rm lim} = [0.15 + (1/r)](0.85 + 10p), \qquad (16.1.12.7)$$

imposed with the proviso that $0.75 \le E_{\rm lim} \le 1.25$. Resolution enhancement is simple: all missing data can optionally be given a value of 1.0, which is the square root of the expectation value of E^2 from Wilson statistics. It can be seen that this procedure always needs a fragment, but this can be very small indeed. Examples include five S atoms in the catalytic domain of chitinase A1 from *Bacillus circulans* WL-12 (Matsumoto *et al.*, 1999) that account for less than 1% of the scattering density and oxidoreductase (Haynes *et al.*, 1994) with less than 0.5% of the scattering power in the initial fragment. In the latter case, the space group is *P*1 so one heavy atom can be placed at the unit-cell origin. Two atoms define the fragment: one was placed at the origin and the second in a position compatible with the Patterson map. The final mean phase error was 31.6°. *ACORN2* is available as part of the *CCP4* package at http://www.ccp4.ac.uk.

16.1.12.2. *IL MILIONE*

The *IL MILIONE* software is a product of the Bari group (Burla *et al.*, 2007). It provides a complete suite of programs for structure solution including software for processing SAD, MAD or SIRAS data or for molecular replacement. We will focus here on the *ab initio* procedures in this package. *Ab initio* phasing uses triplets and tangent procedures or Patterson methods. Direct-space refinement using density modification is employed along with the use of a resolution extension procedure. For the initial phasing, triplet invariants are evaluated by means of the P10 formula (Cascarano *et al.*, 1984). The tangent formula [equation (16.1.4.1)] is used in conjunction with these triplet-phase estimates starting with random phases and multiple starting points. An early figure of merit (eFOM) is calculated for each tangent trial and only the best trial solutions based on this are submitted to direct-space refinement. When misplaced molecular fragments are present, the structures can often be solved by the *RELAX* procedure (Burla *et al.*, 2003). In this procedure, the phases of a trial solution obtained in the correct space group are extended and refined in *P*1 by direct-space techniques. The appropriate figures of merit are used to determine the appropriate vector shift to operate on the fragment.

Patterson deconvolution may also be used in conjunction with direct methods. A superposition minimum function is used. The first peak from this procedure is always used in the phasing process. For each of the remaining peaks (the number of which depends on the size of the structure to be solved and on its data resolution), a set of phases is obtained which is ranked by a specific early figure of merit (pFOM) defined as

$$\mathrm{pFOM} = \sigma/R(\Phi), \qquad (16.1.12.8)$$

where σ is the usual standard deviation of the electron-density map and $R(\Phi)$ is the minimal function [equation (16.1.4.2)]. Irrespective of whether direct or Patterson methods are used, direct-space refinement techniques consist of cycles of electron-density modification (in which only a small fraction of the electron densities are inverted to obtain new phases), and a mask from molecular envelope calculations is applied. The correct solution is identified by a final figure of merit (fFOM), and the program automatically stops when fFOM exceeds a given threshold that depends on data resolution and structural complexity. The Patterson deconvolution methods proved to be, by far, the most efficient ones for large structures and, therefore, have been chosen as the default procedure in this case. They extended the size of the macromolecular structures that are solvable *ab initio* to more than 6000 non-H atoms in the asymmetric unit, provided that at least one calcium atom is present in the asymmetric unit and atomic resolution data are available (Burla *et al.*, 2007).

In favourable circumstances, *IL MILIONE* is also able to solve protein structures with data resolution up to 1.4–1.5 Å and to provide interpretable electron-density maps. The program has been tested using about 100 structures randomly taken from among those in the PDB with resolution better than 1.6 Å. It was able to solve all the test structures that had atomic resolution data, less than 2000 non-H atoms in the asymmetric unit (Nasym), and atoms heavier than calcium present (Zmax > 20). The solution efficiency is reduced to 84% for structures with atomic resolution data, Zmax > 20 and Nasym > 2000, and it is reduced further when these conditions are not fully met. In the presence of atoms as heavy as Ho, Au, Hg or Yb, solutions of structures composed of more than 1000 atoms have been achieved at resolutions as low as 2.0 Å. Finally, it was successful even at 1.65 Å for a case containing up to 7890 non-hydrogen atoms in the asymmetric unit (Caliandro *et al.*, 2008).

IL MILIONE can also apply direct methods to SIR and MIR data. Two different approaches may be followed for protein crystal-structure solution from isomorphous data (up to five derivatives may be used). The triplet phase invariants are estimated *via* the conditional probability distribution function,

$$P(\Phi_p|E_{p\mathbf{H}}, E_{p\mathbf{K}}, E_{p\mathbf{H+K}}, E_{d\mathbf{H}}, E_{d\mathbf{K}}, E_{d\mathbf{H+K}}) = [2\pi I_0(G\cos\Phi_p)] \qquad (16.1.12.9)$$

(Hauptman, 1982*a*; Giacovazzo *et al.*, 1988, 1996), where Φ_p is the triplet phase of the protein and

$$G = 2(\sigma^3/\sigma_2^{3/2})_p E_{p\mathbf{H}} E_{p\mathbf{K}} E_{p\mathbf{H+K}} + 2q(\sigma^3/\sigma_2^{3/2})_{\mathbf{H}} \Delta_{\mathbf{H}} \Delta_{\mathbf{K}} \Delta_{\mathbf{H+K}}$$
$$\Delta = (F_d - F_p)/\Sigma_H^{1/2}. \qquad (16.1.12.10)$$

The factor q takes into account lack of isomorphism and measurement errors, and the Δ parameters are isomorphous differences normalized with respect to the heavy-atom structure. Φ_p is expected to be close to 0 or π according to whether G is positive or negative. A starting set of phases is generated by a random process, a weighted tangent formula is applied to these phases and various trials are produced among which the correct solution may be found by a suitable figure of merit. If multiple derivatives are available, the program is able to estimate automatically, for each derivative, the scattering power of the heavy-atom structure and also to suggest which is the best derivative. The *IL MILIONE* package can be obtained from http://www.ic.cnr.it.

16.1.12.3. SHELX

The *SHELX* family of programs is widely used for small- to medium-sized structure solution and refinement. The family also contains three programs that are extensively used in macromolecular crystallography: *SHELXC*, *SHELXD* and *SHELXE*. For an overview of the *SHELX* system, see Sheldrick (2008). *SHELXC* is a housekeeping program designed to prepare the necessary files for *SHELXD* and *SHELXE*. *SHELXD* (Sheldrick, 1998; Schneider & Sheldrick, 2002; Usón & Sheldrick, 1999) is employed both for substructure solution and for *ab initio* direct methods for atomic resolution data as described elsewhere in this chapter. Fu *et al.* (2007) have shown how to adapt it to multiple CPU systems. *SHELXE* (Sheldrick, 2002, 2008, 2010) improves experimental phases from SAD, SIRAS or MAD data or starting phases from molecular replacement by iterative density modification and autotracing. *SHELX* can be obtained at http://shelx.uni-ac.gwdg.de/SHELX/.

16.1.12.4. SnB and BnP

SnB was the first program to solve small macromolecules *ab initio*, using a global cost function [equation (16.1.4.2)] that reflects how well the calculated phases fit the expected distribution of the triplets. It is fully described elsewhere in this chapter and is an effective tool in structure and substructure determination. Versions are available for multiple CPU systems (Rappleye *et al.*, 2002) and computational grids (Miller *et al.*, 2007). It is also available as part of the *BnP* package (Weeks *et al.*, 2002) that was produced in collaboration with the Biocrystallography Laboratory at the University of Pittsburgh for the experimental phasing of macromolecules. *SnB* is available from http://www.hwi.buffalo.edu/SnB/ and *BnP* from http://www.hwi.buffalo.edu/BnP/.

16.1.12.5. HySS

The substructure solution program *HySS* (Grosse-Kunstleve & Adams, 2003), which is part of the *PHENIX* package (Adams *et al.*, 2007), is closely modelled on *SHELXD* but was implemented using the cctbx libraries (Grosse-Kunstleve *et al.*, 2002). The main differences to *SHELXD* are (1) the translational search for two-atom fragments is performed by Fourier methods followed by a peak search rather than a random search, (2) the use of the tangent formula in reciprocal space is replaced by squaring the density in real space, and (3) several termination criteria are implemented so that the program can stop when the structure appears to be solved. The *PHENIX* package can be obtained at http://www.phenix-online.org/.

16.1.12.6. SUPERFLIP: charge flipping

Charge flipping is a disturbingly simple dual-space algorithm (Oszlányi & Sütő, 2004, 2005, 2008). It uses as input only the cell parameters of the structure, the reflection indices and the intensities. The intensities can be corrected for thermal motion *via* an overall temperature factor if required, and this is often beneficial. Neither chemical information nor the symmetry is explicitly used in the structure solution process. The electron density is sampled on a discrete rectangular grid of pixels with values ρ_i, $i = 1, N_{\rm pix}$. The algorithm proceeds iteratively. To begin the process, a starting set of structure factors is created by combining the experimental structure-factor amplitudes with random phases. Each iteration or cycle (numbered n) involves four steps:

(1) A trial electron density $\rho^{(n)}$ is obtained by inverse Fourier transform of the structure factors in the usual way.

(2) A modified density $g^{(n)}$ is obtained from $\rho^{(n)}$ by reversing the sign (charge flipping) of all density pixels with density below a certain positive threshold δ as follows:

$$\begin{aligned} g_i^{(n)} &= \rho_i^{(n)} \quad \text{if} \quad \rho_i^{(n)} > \delta, \\ g_i^{(n)} &= -\rho_i^{(n)} \quad \text{if} \quad \rho_i^{(n)} \leq \delta. \end{aligned} \qquad (16.1.12.11)$$

(3) Modified structure factors are obtained by Fourier transform of $g^{(n)}$,

$$G_{\mathbf{H}}^{(n)} = FT[g^{(n)}]. \qquad (16.1.12.12)$$

(4) The structure factors $F_{\mathbf{H}}^{(n+1)}$ are obtained from $F_{\mathbf{H}}^{(n+1)}$ and $G_{\mathbf{H}}^{(n+1)} = |G_{\mathbf{H}}^{(n+1)}| \exp(2\pi i \varphi_{\mathbf{H}}^G)$ as follows:

   (*a*) $F_{\mathbf{H}}^{(n+1)} = |F_{\mathbf{H}}| \exp(2\pi i \varphi_{\mathbf{H}}^G)$ for $|F_{\mathbf{H}}|$ observed and strong.

   (*b*) $F_{\mathbf{H}}^{(n+1)} = |G_{\mathbf{H}}^{(n)}| \exp[2\pi i (\varphi_{\mathbf{H}}^G + 0.25)]$ for $|F_{\mathbf{H}}|$ observed and weak. In other words, for these reflections, calculated moduli are accepted unchanged and calculated phases are shifted by a constant $\Delta\varphi = \pi/2$. This means that the observed data of weak reflections are not used actively in the process, except for the knowledge that they are indeed weak. Experience shows that about 20–40% of all reflections can be considered weak. This use of the phase shifting of the weak reflections significantly improves the performance of the algorithm in cases of more complex structures (Oszlányi & Sütő, 2005); in some cases the success rate is increased by a factor of ten, in other cases a previously unsolvable structure becomes solvable by the modified algorithm.

   (*c*) $F_{\mathbf{H}}^{(n+1)} = 0$ for $|F_{\mathbf{H}}|$ unobserved.

   (*d*) $F_{\mathbf{H}}^{(n+1)} = G_{\mathbf{H}}^{(n)}$ for $\mathbf{H} = 0$. In other words, the value of F_{000} is not fixed.

The new set of structure factors enters the next cycle or iteration. The cycles are repeated until the calculation converges. Progress is monitored by a conventional R factor where a small change in R signals convergence. The parameter δ is the main variable of the iteration, and its value can be critical. It must often be determined by trial and error, but this search can be automated. The second variable parameter of the algorithm is the proportion of the reflections considered weak in each cycle.

The algorithm seeks a Fourier map that is stable against repeated flipping of all density regions below δ. Obviously, a large number of missing reflections will make the algorithm less efficient, because the missing reflections are assigned a zero amplitude, which induces large termination ripples in the Fourier map. The underlying assumption of the algorithm, that the density is close to zero in large regions of the unit cell and positive in small parts of the unit cell, is no longer fulfilled and the algorithm fails. The question of incomplete data has been addressed by Palatinus *et al.* (2007). They show that the missing data can be approximated on the basis of the Patterson map of the unknown structure optimized by the maximum-entropy method. Structures that could not be solved by the original charge-flipping algorithm can be solved in this way. For small molecules, 50% or more of the reflections can be missing, and the structure can still be reconstructed by charge flipping. The situation for macromolecules is less clear.

Symmetry is an important issue. Surprisingly, in the charge-flipping method, all structures are solved in space group *P*1, and all symmetry constraints are ignored. Attempts to impose symmetry usually damage the process fatally. The disadvantage of this is that the charge density of the whole unit cell must be determined, and not just that of the asymmetric unit. Furthermore, the symmetry elements must be located once a solution has been found. A computer program, *SUPERFLIP* (Palatinus & Chapuis, 2007), and a Java applet that demonstrates the procedure in two dimensions are freely available for download at http://escher.epfl.ch/flip/.

The charge-flipping method has been adapted to proteins (Dumas & van der Lee, 2008) and applied to a *P*1 structure with 7111 atoms [*i.e.* liver alcohol dehydogenase in complex with NADH and Cd-DMSO: 5866 protein atoms, 1241 waters and 4 Cd atoms (Meijers *et al.*, 2007)]. In common with other methods described in this chapter, charge flipping is much more effective for data to very high resolution (in this case 1.0 Å) and especially for structures containing heavier atoms. The method can also, in principle, be used for substructure determination; the solution of known substructures with as many as 120 unique Se atoms is reported in the same paper.

16.1.12.7. CRUNCH2 – Karle–Hauptman determinants

The program *CRUNCH2* is quite different to the other programs mentioned in this section. With the exception of some *E*-map recycling at the end to complete a substructure, *CRUNCH2* operates entirely in reciprocal space by maximizing higher-order Karle–Hauptman determinants (Karle & Hauptman, 1950; de Gelder *et al.*, 1993). It is incorporated into the automated *CRANK* pipeline for macromolecular structure solution (Ness *et al.*, 2004). The quality of the substructure solutions obtained appears to be at least as good as those from the dual-space programs, but it may be slower for large substructures.

16.1.13. Conclusions and the grand challenge

In practice, the main use of direct methods in macromolecular crystallography is to obtain substructures using SAD and MAD data where the limitations of the method can be relaxed. There are, of course, a few structures solved *ab initio*, but they are relatively uncommon. There is a grand challenge here: to solve *ab initio* macromolecular structures using the native data alone at resolutions more typical for macromolecules without the need for specific prior structural knowledge.

The extensive (and successful) use of atomicity constraints both in real space (peak picking) and reciprocal space (tangent formula and minimal function) make it difficult to overcome the need for atomic resolution data in the *Shake-and-Bake* methods. At lower resolution, the atomicity constraint should be replaced by another based on the recurrence of model fragments that can be predicted *a priori* from the protein sequence (*e.g.* small polyalanine α-helices, β-sheets, cofactors, bases, disulfide bridges *etc.*). The effectiveness of a very small, yet accurate, fraction of the total scattering mass in the form of a fragment or heavy atoms is apparent from the results of *ACORN2* and *IL MILIONE*.

Shortly before this chapter went to press, a paper by the Usón group (Rodríguez *et al.*, 2009) showed a possible way ahead in the case of equal-atom structures, by exploiting general features of protein secondary structure. In its current form, the method requires that the protein is at least 20% α-helical and diffracts to 2.0 Å or better, requirements that would be fulfilled by at least a quarter of the protein crystal structures deposited in the PDB. The method was successfully applied to four test structures and one previously unsolved 222 amino-acid structure that diffracted to 1.95 Å and had resisted all previous attempts at solution by molecular replacement and experimental phasing. The method exploits the power of the molecular-replacement program *PHASER* (McCoy *et al.*, 2007) to search for multiple copies of (for example) 14-residue α-helices with data truncated to 2.5 Å, retaining several thousand 'best' solutions at each stage as judged by maximum-likelihood criteria. These potential multi-helix solutions are all input into a new version of the program *SHELXE* (Sheldrick, 2010) that applies density modification and main-chain tracing iteratively. At some point, depending on the size of the structure and the quality of the data, but typically for a trial structure consisting of three or four α-helices making up some 12% of the structure, the autotracing locks in and gives a relatively complete backbone trace that can be immediately recognized both by the number of connected residues traced and a correlation coefficient between the calculated and observed *E* values. A multiple CPU computer grid is essential for performing these numerically intensive calculations in parallel, and the whole branching and pruning operation is performed under the control of the program *ARCIMBOLDO*. This approach is still at an early stage and should benefit from fine-tuning and the inevitable future increases in computer power, but it clearly has the potential to become a main-stream *ab initio* method for the solution of protein structures.

The development, in Buffalo, of the *Shake-and-Bake* algorithm and the *SnB* program has been supported by grants GM-46733 from NIH and ACI-9721373 from NSF, and computing time from the Center for Computational Research at SUNY Buffalo. HAH, CMW and RM would also like to thank the following individuals: Chun-Shi Chang, Ashley Deacon, George DeTitta, Adam Fass, Steve Gallo, Hanif Khalak, Andrew Palumbo, Jan Pevzner, Thomas Tang and Hongliang Xu, who have aided the development of *SnB*, and Steve Ealick, P. Lynne Howell, Patrick Loll, Jennifer Martin and Gil Privé, who have generously supplied data sets. The development, in Göttingen, of *SHELXD* has been supported by the BIOXHIT Consortium and the HCM Institutional Grant ERB CHBG CT 940731 from the European Commission. GMS and IU wish to thank Thammarat Aree, Gábor Bunkóczi, Zbigniew Dauter, Judit É. Debreczeni, Judith

Flippen-Anderson, Carlos Frazão, Katrin Gessler, Håkon Hope, Jörg Kärcher, Peter Kuhn, Victor Lamzin, David Langs, Christopher Lehmann, Peer Mittl, Emilio Parisini, Erich Paulus, Ehmke Pohl, Thierry Prange, Joe Reibenspiess, Martina Schäfer, Thomas Schneider, Markus Teichert, László Vértesy and Martin Walsh for discussions and/or generously providing data for structures referred to in this manuscript.

Chapter 16.2. The maximum-entropy method

G. Bricogne

16.2.1. Introduction

The modern concept of entropy originated in the field of statistical thermodynamics, in connection with the study of large material systems in which the number of internal degrees of freedom is much greater than the number of externally controllable degrees of freedom. This concept played a central role in the process of building a quantitative picture of the multiplicity of microscopic states compatible with given macroscopic constraints, as a measure of how much remains unknown about the detailed fine structure of a system when only macroscopic quantities attached to that system are known. The collection of all such microscopic states was introduced by Gibbs under the name 'ensemble', and he deduced his entire formalism for statistical mechanics from the single premise that the equilibrium picture of a material system under given macroscopic constraints is dominated by that configuration which can be realized with the greatest combinatorial multiplicity (*i.e.* which has maximum entropy) while obeying these constraints.

The notions of ensemble and the central role of entropy remained confined to statistical mechanics for some time, then were adopted in new fields in the late 1940s. Norbert Wiener studied Brownian motion, and subsequently time series of random events, by similar methods, considering in the latter an ensemble of messages, *i.e.* 'a repertory of possible messages, and over that repertory a measure determining the probability of these messages' (Wiener, 1949). At about the same time, Shannon created information theory and formulated his fundamental theorem relating the entropy of a source of random symbols to the capacity of the channel required to transmit the ensemble of messages generated by that source with an arbitrarily small error rate (Shannon & Weaver, 1949). Finally, Jaynes (1957, 1968, 1983) realized that the scope of the principle of maximum entropy could be extended far beyond the confines of statistical mechanics or communications engineering, and could provide the basis for a general theory (and philosophy) of statistical inference and 'data processing'.

The relevance of Jaynes' ideas to probabilistic direct methods was investigated by the author (Bricogne, 1984). It was shown that there is an intimate connection between the maximum-entropy method and an enhancement of the probabilistic techniques of conventional direct methods known as the 'saddlepoint method', some aspects of which have already been dealt with in Section 1.3.4.5.2 in Chapter 1.3 of *IT* B (Bricogne, 2008).

16.2.2. The maximum-entropy principle in a general context

16.2.2.1. Sources of random symbols and the notion of source entropy

Statistical communication theory uses as its basic modelling device a discrete source of random symbols, which at discrete times $t = 1, 2, \ldots$, randomly emits a 'symbol' taken out of a finite alphabet $\mathcal{A} = \{s_i | i = 1, \ldots, n\}$. Sequences of such randomly produced symbols are called 'messages'.

An important numerical quantity associated with such a discrete source is its *entropy per symbol H*, which gives a measure of the amount of uncertainty involved in the choice of a symbol. Suppose that successive symbols are independent and that symbol i has probability q_i. Then the general requirements that H should be a continuous function of the q_i, should increase with increasing uncertainty, and should be additive for independent sources of uncertainty, suffice to define H uniquely as

$$H(q_1, \ldots, q_n) = -k \sum_{i=1}^{n} q_i \log q_i, \qquad (16.2.2.1)$$

where k is an arbitrary positive constant [Shannon & Weaver (1949), Appendix 2] whose value depends on the unit of entropy chosen. In the following we use a unit such that $k = 1$.

These definitions may be extended to the case where the alphabet $\mathcal{A}$ is a continuous space endowed with a uniform measure μ: in this case the entropy per symbol is defined as

$$H(q) = -\int_{\mathcal{A}} q(\mathbf{s}) \log q(\mathbf{s}) \, \mathrm{d}\mu(\mathbf{s}), \qquad (16.2.2.2)$$

where q is the probability density of the distribution of symbols with respect to measure μ.

16.2.2.2. The meaning of entropy: Shannon's theorems

Two important theorems [Shannon & Weaver (1949), Appendix 3] provide a more intuitive grasp of the meaning and importance of entropy:

(1) H is approximately the logarithm of the reciprocal probability of a typical long message, divided by the number of symbols in the message; and

(2) H gives the rate of growth, with increasing message length, of the logarithm of the number of reasonably probable messages, regardless of the precise meaning given to the criterion of being 'reasonably probable'.

The entropy H of a source is thus a direct measure of the strength of the restrictions placed on the permissible messages by the distribution of probabilities over the symbols, lower entropy being synonymous with greater restrictions. In the two cases above, the maximum values of the entropy $H_{\max} = \log n$ and $H_{\max} = \log \mu(\mathcal{A})$ are reached when all the symbols are equally probable, *i.e.* when q is a uniform probability distribution over the symbols. When this distribution is not uniform, the usage of the different symbols is biased away from this maximum freedom, and the entropy of the source is lower; by Shannon's theorem (2), the number of 'reasonably probable' messages of a given length emanating from the source decreases accordingly.

The quantity that measures most directly the strength of the restrictions introduced by the non-uniformity of q is the difference $H(q) - H_{\max}$, since the proportion of N-atom random structures which remain 'reasonably probable' in the ensemble of the corresponding source is $\exp\{N[H(q) - H_{\max}]\}$. This difference may be written (using continuous rather than discrete distributions)

$$H(q) - H_{\max} = -\int_{\mathcal{A}} q(\mathbf{s}) \log[q(\mathbf{s})/m(\mathbf{s})] \, \mathrm{d}\mu(\mathbf{s}), \qquad (16.2.2.3)$$

Copyright © 2012 International Union of Crystallography

where $m(\mathbf{s})$ is the uniform distribution which is such that $H(m) = H_{\max} = \log \mu(\mathcal{A})$.

16.2.2.3. Jaynes' maximum-entropy principle

From the fundamental theorems just stated, which may be recognized as Gibbs' argument in a different guise, Jaynes' own maximum-entropy argument proceeds with striking lucidity and constructive simplicity, along the following lines:

(1) experimental observation of, or 'data acquisition' on, a given system enables us to progress from an initial state of uncertainty to a state of lesser uncertainty about that system;
(2) uncertainty reflects the existence of numerous possibilities of accounting for the available data, viewed as constraints, in terms of a physical model of the internal degrees of freedom of the system;
(3) new data, viewed as new constraints, reduce the range of these possibilities;
(4) conversely, any step in our treatment of the data that would further reduce that range of possibilities amounts to applying extra constraints (even if we do not know what they are) which are not warranted by the available data;
(5) hence Jaynes's rule: '*The probability assignment over the range of possibilities* [*i.e.* our picture of residual uncertainty] *shall be the one with maximum entropy consistent with the available data, so as to remain maximally non-committal with respect to the missing data*'.

The only requirement for this analysis to be applicable is that the 'ranges of possibilities' to which it refers should be representable (or well approximated) by ensembles of abstract messages emanating from a random source. The entropy to be maximized is then the entropy per symbol of that source.

The final form of the maximum-entropy criterion is thus that $q(\mathbf{s})$ should be chosen so as to maximize, under the constraints expressing the knowledge of newly acquired data, its entropy

$$\mathcal{S}_m(q) = -\int_V q(\mathbf{s}) \log[q(\mathbf{s})/m(\mathbf{s})]\, \mathrm{d}\mu(\mathbf{s}) \qquad (16.2.2.4)$$

relative to the 'prior prejudice' $m(\mathbf{s})$ which maximizes H in the absence of these data.

16.2.2.4. Jaynes' maximum-entropy formalism

Jaynes (1957) solved the problem of explicitly determining such maximum-entropy distributions in the case of general linear constraints, using an analytical apparatus first exploited by Gibbs in statistical mechanics.

The maximum-entropy distribution $q^{\rm ME}(\mathbf{s})$, under the prior prejudice $m(\mathbf{s})$, satisfying the linear constraint equations

$$\mathcal{C}_j(q) \equiv \int_{\mathcal{A}} q(\mathbf{s}) C_j(\mathbf{s})\, \mathrm{d}\mu(\mathbf{s}) = c_j \quad (j = 1, 2, \ldots, M), \qquad (16.2.2.5)$$

where the $\mathcal{C}_j(q)$ are linear *constraint functionals* defined by given *constraint functions* $C_j(\mathbf{s})$, and the c_j are given *constraint values*, is obtained by maximizing with respect to q the relative entropy defined by equation (16.2.2.4). An extra constraint is the normalization condition

$$\mathcal{C}_0(q) \equiv \int_{\mathcal{A}} q(\mathbf{s})\ 1\ \mathrm{d}\mu(\mathbf{s}) = 1, \qquad (16.2.2.6)$$

to which it is convenient to give the label $j = 0$, so that it can be handled together with the others by putting $C_0(\mathbf{s}) = 1$, $c_0 = 1$.

By a standard variational argument, this constrained maximization is equivalent to the unconstrained maximization of the functional

$$\mathcal{S}_m(q) + \sum_{j=0}^{M} \lambda_j \mathcal{C}_j(q), \qquad (16.2.2.7)$$

where the λ_j are Lagrange multipliers whose values may be determined from the constraints. This new variational problem is readily solved: if $q(\mathbf{s})$ is varied to $q(\mathbf{s}) + \delta q(\mathbf{s})$, the resulting variations in the functionals $\mathcal{S}_m$ and $\mathcal{C}_j$ will be

$$\begin{aligned} \delta\mathcal{S}_m &= \int_{\mathcal{A}} \{-1 - \log[q(\mathbf{s})/m(\mathbf{s})]\}\, \delta q(\mathbf{s})\, \mathrm{d}\mu(\mathbf{s}) \quad \text{and} \\ \delta\mathcal{C}_j &= \int_{\mathcal{A}} \{C_j(\mathbf{s})\}\, \delta q(\mathbf{s})\, \mathrm{d}\mu(\mathbf{s}), \end{aligned} \qquad (16.2.2.8)$$

respectively. If the variation of the functional (16.2.2.7) is to vanish for arbitrary variations $\delta q(\mathbf{s})$, the integrand in the expression for that variation from (16.2.2.8) must vanish identically. Therefore the maximum-entropy density distribution $q^{\rm ME}(\mathbf{s})$ satisfies the relation

$$-1 - \log[q(\mathbf{s})/m(\mathbf{s})] + \sum_{j=0}^{M} \lambda_j C_j(\mathbf{s}) = 0 \qquad (16.2.2.9)$$

and hence

$$q^{\rm ME}(\mathbf{s}) = m(\mathbf{s}) \exp(\lambda_0 - 1) \exp\left[\sum_{j=1}^{M} \lambda_j C_j(\mathbf{s})\right]. \qquad (16.2.2.10)$$

It is convenient now to separate the multiplier λ_0 associated with the normalization constraint by putting

$$\lambda_0 - 1 = -\log Z, \qquad (16.2.2.11)$$

where Z is a function of the other multipliers $\lambda_1, \ldots, \lambda_M$. The final expression for $q^{\rm ME}(\mathbf{s})$ is thus

$$q^{\rm ME}(\mathbf{s}) = \frac{m(\mathbf{s})}{Z(\lambda_1, \ldots, \lambda_M)} \exp\left[\sum_{j=1}^{M} \lambda_j C_j(\mathbf{s})\right]. \qquad (\text{ME1})$$

The values of Z and of $\lambda_1, \ldots, \lambda_M$ may now be determined by solving the initial constraint equations. The normalization condition demands that

$$Z(\lambda_1, \ldots, \lambda_M) = \int_{\mathcal{A}} m(\mathbf{s}) \exp\left[\sum_{j=1}^{M} \lambda_j C_j(\mathbf{s})\right] \mathrm{d}\mu(\mathbf{s}). \qquad (\text{ME2})$$

The generic constraint equations (16.2.2.5) determine $\lambda_1, \ldots, \lambda_M$ by the conditions that

$$\int_{\mathcal{A}} [m(\mathbf{s})/Z] \exp\left[\sum_{k=1}^{M} \lambda_k C_k(\mathbf{s})\right] C_j(\mathbf{s})\, \mathrm{d}\mu(\mathbf{s}) = c_j \qquad (16.2.2.12)$$

for $j = 1, 2, \ldots, M$. But, by Leibniz's rule of differentiation under the integral sign, these equations may be written in the compact form

$$\frac{\partial(\log Z)}{\partial\lambda_j} = c_j \quad (j = 1, 2, \ldots, M). \qquad (\text{ME3})$$

Equations (ME1), (ME2) and (ME3) constitute the *maximum-entropy equations*.

The maximal value attained by the entropy is readily found:

$$\begin{aligned} \mathcal{S}_m(q^{\rm ME}) &= -\int_{\mathcal{A}} q^{\rm ME}(\mathbf{s}) \log\big[q^{\rm ME}(\mathbf{s})/m(\mathbf{s})\big]\, \mathrm{d}\mu(\mathbf{s}) \\ &= -\int_{\mathcal{A}} q^{\rm ME}(\mathbf{s}) \left[-\log Z + \sum_{j=1}^{M} \lambda_j C_j(\mathbf{s})\right] \mathrm{d}\mu(\mathbf{s}), \end{aligned}$$

i.e. using the constraint equations

$$\mathcal{S}_m(q^{\rm ME}) = \log Z - \sum_{j=1}^{M} \lambda_j c_j. \qquad (16.2.2.13)$$

The latter expression may be rewritten, by means of equations (ME3), as

$$\mathcal{S}_m(q^{\rm ME}) = \log Z - \sum_{j=1}^{M} \lambda_j \frac{\partial(\log Z)}{\partial \lambda_j}, \qquad (16.2.2.14)$$

which shows that, in their dependence on the λ's, the entropy and log Z are related by Legendre duality.

Jaynes' theory relates this maximal value of the entropy to the prior probability $\mathcal{P}(\mathbf{c})$ of the vector **c** of simultaneous constraint values, *i.e.* to the size of the sub-ensemble of messages of length N that fulfil the constraints embodied in (16.2.2.5), relative to the size of the ensemble of messages of the same length when the source operates with the symbol probability distribution given by the prior prejudice m. Indeed, it is a straightforward consequence of Shannon's second theorem (Section 16.2.2) as expressed in equation (16.2.2.3) that

$$\mathcal{P}^{\rm ME}(\mathbf{c}) \propto \exp(\mathcal{S}), \qquad (16.2.2.15)$$

where

$$\mathcal{S} = \log Z^N - \lambda \cdot \mathbf{c} = N\mathcal{S}_m(q^{\rm ME}) \qquad (16.2.2.16)$$

is the total entropy for N symbols.

16.2.3. Adaptation to crystallography

16.2.3.1. *The random-atom model*

The standard setting of probabilistic direct methods (Hauptman & Karle, 1953; Bertaut, 1955*a*,*b*; Klug, 1958) uses implicitly as its starting point a source of random atomic positions. This can be described in the terms introduced in Section 16.2.2.1 by using a continuous alphabet $\mathcal{A}$ whose symbols **s** are fractional coordinates **x** in the asymmetric unit of the crystal, the uniform measure μ being the ordinary Lebesgue measure $\mathrm{d}^3\mathbf{x}$. A message of length N generated by that source is then a random N-equal-atom structure.

16.2.3.2. *Conventional direct methods and their limitations*

The traditional theory of direct methods assumes a *uniform* distribution $q(\mathbf{x})$ of random atoms and proceeds to derive joint distributions of structure factors belonging to an N-atom random structure, using the asymptotic expansions of Gram–Charlier and Edgeworth. These methods have been described in Section 1.3.4.5.2.2 of *IT* B (Bricogne, 2008) as examples of applications of Fourier transforms. The reader is invited to consult this section for terminology and notation. These joint distributions of complex structure factors are subsequently used to derive conditional distributions of phases when the amplitudes are assigned their observed values, or of a subset of complex structure factors when the others are assigned certain values. In both cases, the *largest* structure-factor amplitudes are used as the conditioning information.

It was pointed out by the author (Bricogne, 1984) that this procedure can be problematic, as the Gram–Charlier and Edgeworth expansions have good convergence properties only in the vicinity of the expectation values of each structure factor: as the atoms are assumed to be uniformly distributed, these series afford an adequate approximation for the joint distribution $\mathcal{P}(\mathbf{F})$ only near the origin of structure-factor space, *i.e.* for *small* values of all the structure amplitudes. It is therefore incorrect to use these local approximations to $\mathcal{P}(\mathbf{F})$ near $\mathbf{F} = \mathbf{0}$ as if they were the global functional form for that function 'in the large' when forming conditional probability distributions involving large amplitudes.

16.2.3.3. *The notion of recentring and the maximum-entropy criterion*

These limitations can be overcome by recognizing that, if the locus $\mathcal{T}$ (a high-dimensional torus) defined by the large structure-factor amplitudes to be used in the conditioning data is too extended in structure-factor space for a single asymptotic expansion of $\mathcal{P}(\mathbf{F})$ to be accurate everywhere on it, then $\mathcal{T}$ should be broken up into sub-regions, and different local approximations to $\mathcal{P}(\mathbf{F})$ should be constructed in each of them. Each of these sub-regions will consist of a 'patch' of $\mathcal{T}$ surrounding a point $\mathbf{F}^* \neq \mathbf{0}$ located on $\mathcal{T}$. Such a point $\mathbf{F}^*$ is obtained by assigning 'trial' phase values to the known moduli, but these trial values do not necessarily have to be viewed as 'serious' assumptions concerning the true values of the phases: rather, they should be thought of as pointing to a patch of $\mathcal{T}$ and to a specialized asymptotic expansion of $\mathcal{P}(\mathbf{F})$ designed to be the most accurate approximation possible to $\mathcal{P}(\mathbf{F})$ on that patch. With a sufficiently rich collection of such constructs, $\mathcal{P}(\mathbf{F})$ can be accurately calculated anywhere on $\mathcal{T}$.

These considerations lead to the notion of *recentring*. Recentring the usual Gram–Charlier or Edgeworth asymptotic expansion for $\mathcal{P}(\mathbf{F})$ away from $\mathbf{F} = \mathbf{0}$, by making trial phase assignments that define a point $\mathbf{F}^*$ on $\mathcal{T}$, is equivalent to using a non-uniform prior distribution of atoms $q(\mathbf{x})$, reproducing the individual components of $\mathbf{F}^*$ among its Fourier coefficients. The latter constraint leaves $q(\mathbf{x})$ highly indeterminate, but Jaynes' argument given in Section 16.2.2.3 shows that there is a uniquely defined 'best' choice for it: it is that distribution $q^{\rm ME}(\mathbf{x})$ having *maximum entropy* relative to a uniform prior prejudice $m(\mathbf{x})$, and having the corresponding values $\mathbf{U}^*$ of the unitary structure factors for its Fourier coefficients. This distribution has the unique property that it rules out as few random structures as possible on the basis of the limited information available in $\mathbf{F}^*$.

In terms of the statistical mechanical language used in Section 16.2.1, the trial structure-factor values $\mathbf{F}^*$ used as constraints would be the macroscopic quantities that can be controlled externally; while the $3N$ atomic coordinates would be the internal degrees of freedom of the system, whose entropy should be a maximum under these macroscopic constraints.

16.2.3.4. *The crystallographic maximum-entropy formalism*

It is possible to solve explicitly the maximum-entropy equations (ME1) to (ME3) derived in Section 16.2.2.4 for the crystallographic case that has motivated this study, *i.e.* for the purpose of constructing $q^{\rm ME}(\mathbf{x})$ from the knowledge of a set of trial structure-factor values $\mathbf{F}^*$. These derivations are given in §3.4 and §3.5 of Bricogne (1984). Extensive relations with the algebraic formalism of traditional direct methods are exhibited in §4, and connections with the theory of determinantal inequalities and with the maximum-determinant rule of Tsoucaris (1970) are studied in §6, of the same paper. The reader interested in these topics is invited to consult this paper, as space limitations preclude their discussion in the present chapter.

16.2.3.5. *Connection with the saddlepoint method*

The saddlepoint method constitutes an alternative approach to the problem of evaluating the joint probability $\mathcal{P}(\mathbf{F}^*)$ of structure factors when some of the moduli in $\mathbf{F}^*$ are large. It is shown in §5 of Bricogne (1984), and in more detail in Section 1.3.4.5.2.2 of Chapter 1.3 of *IT* B (Bricogne, 2008), that there is complete equivalence between the maximum-entropy approach to the phase problem and the classical probabilistic approach by the method of joint distributions, provided the latter is enhanced by the adoption of the saddlepoint approximation.

Chapter 16.3. *Ab initio* phasing of low-resolution Fourier syntheses

V. Y. Lunin, A. G. Urzhumtsev and A. Podjarny

16.3.1. Introduction

Low-resolution macromolecular structural information may be obtained for non-crystalline macromolecular objects by electron microscopy (see Chapter 19.6 and references therein) or small-angle X-ray scattering (see Chapter 19.3 and references therein), or by using X-ray free-electron lasers (Chapman *et al.*, 2011; Seibert *et al.*, 2011) and iterative density-reconstruction techniques (Sayre, 2008). While giving similar structural information, low-resolution crystallographic images are a more natural starting point on the way towards atomic models. The need to work at low resolution may be due to the limited diffraction power of the crystals or the failure of standard phasing methods.

A number of techniques have been suggested to estimate the phases of structure factors using various complementary sources of information, specific to a given crystal:

(i) Phasing by isomorphous replacement or anomalous scattering techniques using heavy atoms or their clusters may lead to good results, ranging from the pioneering structures reported at nearly 6 Å resolution (Green *et al.*, 1954; Perutz *et al.*, 1960; Black *et al.*, 1962) to viruses (for example, Harrison & Jack, 1975) and ribosomes (Ban *et al.*, 1998). However, working at low resolution requires special effort, high data quality and several sets of structure-factor magnitudes.

(ii) Molecular-replacement-type low-resolution searches can be carried out using conventional models, more or less coarsely (Valegård *et al.*, 1991; Jamrog *et al.*, 2003), with simplified models or with molecular envelopes (Jack *et al.*, 1975; Rayment *et al.*, 1982; Urzhumtsev & Podjarny, 1995; Hao, 2006). The simplified models, roughly reproducing molecular shapes obtained previously, may be a spherical shell for viruses (for example Johnson *et al.*, 1976; Chapman *et al.*, 1992), a sphere or a cylindrical shell for proteins and their complexes (Podjarny *et al.*, 1987; Harris, 1995; Andersson & Hovmöller, 1996; Lunin *et al.*, 2001), or several cylinders for α-helical proteins (Kalinin, 1980; Strop *et al.*, 2007).

(iii) Phasing techniques can be based on the different average diffraction power of the proteins, nucleic acids and bulk solvent, naturally or artificially introduced (Bragg & Perutz, 1952; Roth *et al.*, 1984; Carter *et al.*, 1990; Fourme *et al.*, 1995; Shepard *et al.*, 2000). These techniques require several crystals and their corresponding diffraction data sets.

(iv) In some cases, the classical direct phasing methods can be formally tried to obtain a molecular envelope at low resolution (Podjarny *et al.*, 1981; Carter *et al.*, 1990). Similarly, the phase triplets obtained experimentally by a three-beam diffraction experiment lead in some cases to relatively low-resolution images (Hölzer *et al.*, 2000).

In this chapter we discuss only *ab initio* phasing methods. By this term we mean a mathematical or computational procedure to estimate the values of the structure-factor phases using a single set of structure-factor magnitudes and only a general type of information, in contrast with most of the methods mentioned above. Low-resolution *ab initio* phasing estimates the phase values of the structure factors of the lowest resolution for a given crystal, from several tens to several hundreds of reflections in total. Depending on the size of the unit cell, a low-resolution Fourier synthesis calculated with these structure factors can show molecular positions in the unit cell, molecular envelopes (at a resolution $d_{\min} \simeq 15$ Å or lower) or secondary-structure elements (when $d_{\min} \simeq 5$–6 Å).

16.3.2. General features of low-resolution images

Low-resolution *ab initio* phasing is usually a laborious procedure. Some features of low-resolution Fourier syntheses increase the difficulties, as follows:

(i) There is a common belief that low-resolution Fourier syntheses represent molecular envelopes when the cutoff level is relatively low and the centres of the molecules when this level is high. In practice, density peaks are often shifted from molecular centres toward regions of close intermolecular contact. Bulk-solvent correction decreases the contrast between two neighbouring peaks and can result in their merging. Also, due to the relatively small number of reflections used in the calculation, a small change in phase can significantly modify the image and the positions of the peaks.

(ii) Low-resolution envelopes cannot represent sharp molecular features accurately enough and thus cannot cover all macromolecular atoms, even when the synthesis is calculated with the exact structure-factor values.

(iii) An increase in the resolution of Fourier maps does not always help to interpret them. For example, an increase in resolution from 16–25 Å to 10–12 Å often makes maps even less suitable for visual inspection, since they stop showing molecular envelope features but do not reveal secondary-structure elements.

(iv) Usually, visual inspection of low-resolution maps does not allow one to choose the correct enantiomer. In addition, the overall features of the flipped map $-\rho(\mathbf{r})$ at very low resolution are often very similar to those of the direct map $\rho(\mathbf{r})$. This might complicate the choice of the correct sign of the map.

(v) Low-resolution Fourier maps are very sensitive to missing reflections, even if their number is small.

(vi) Maps calculated with too few reflections may show a superposition of images corresponding to different choices of the origin.

(vii) The determination of twinning and the correct choice of space group are especially complicated at low resolution.

16.3.3. Low-resolution phasing

If additional experimental information cannot be used to solve the phase problem, then the search for the correct structure has to be based on some general features of the true phase set. Such features can be formulated as a selection criterion (‘score

Copyright © 2012 International Union of Crystallography

function', 'figure of merit' *etc.*) that may have a qualitative or a quantitative form (Gilmore, 2000; Lunin, Lunina, Petrova *et al.*, 2000). In the following, we use the term 'selection criterion' to reflect a quality of the phase set as a whole, and we reserve the term 'figure of merit' to estimate the accuracy of an individual phase.

Unfortunately, no selection criterion suggested so far identifies the true phase set unambiguously (Lunin, Lunina *et al.*, 2002). Therefore, the phase problem cannot be solved by a simple search for the best value of a selection criterion. Nevertheless, it has been shown that many criteria improve the ensemble of phase sets by retaining good phase sets, *i.e.* those close to the true values. In other words, when the starting ensemble of phase sets (*e.g.* randomly generated) is reduced to those phase sets with a reasonable value of a selection criterion, the percentage of good phase sets increases. Therefore, a multifiltering cyclic phasing procedure was suggested (Lunin *et al.*, 1990):

(i) A set of reflections $S_{\rm work}$ is chosen for phasing.
(ii) A large number of random phase sets are generated either directly or using models.
(iii) The generated ensemble of phase sets is filtered by applying different selection rules.
(iv) The phase sets that fit all selection rules (the selected phase sets) form the output of the cycle.

The output is used to produce estimates of individual phase values (averaged or median) and to modify the mode of generation of random phases in the next cycle. The cycle is repeated several times, varying the phase-generating mode and the selection rules, extending the set of reflections $S_{\rm work}$ to be phased *etc.*

A key feature of this procedure is that at every cycle we do not search for the phase set with the best possible fit to the selection rules, but we filter out obviously poor phase sets.

16.3.4. Phase generation and selection

16.3.4.1. *Generation of the phase sets*

This step defines how the configuration space of all phase sets is explored. First, all phases may be considered as independent variables. At the beginning of phasing when no information is available, all values are considered equally probable. When some phase information for a reflection is available, for example in the form of a probability distribution, it may be used to generate new random phases, taking into account the restrictions of the space-group symmetry. Second, the phases may be calculated through models. For example, a phase set may be calculated from a model composed of a small number of large Gaussian spheres ('globs'), the coordinates of which are now considered as primary random variables (Lunin *et al.*, 1995; Guo *et al.*, 2000). The sphere coordinates may be generated uniformly in the whole unit cell at the very beginning of phasing and inside a molecular mask later, when some phase information becomes available. The use of models parameterizes the phase space and thus reduces the search. At the same time, if the models are inappropriate, they cannot generate a good approximation to the correct solution.

A further development of the second approach is a multiple-model-based molecular-replacement search (Buehler *et al.*, 2009). In this case, the output of the procedure is no longer the rigid-body parameters of the search model, as in traditional molecular replacement, but a phase set.

16.3.4.2. *Search targets – overview*

Two ways of generating phase variants lead to two different types of search targets. First, the phase selection can be applied at the level of the Fourier maps. For each trial phase set, a Fourier map can be calculated using experimental magnitudes. Then, the selection rule checks whether it has the features of a correct macromolecular Fourier synthesis or not. This approach has the advantage that it avoids model-related problems. If the phase sets are calculated from a model, then the corresponding calculated structure-factor magnitudes are also available. Their similarity to the experimental ones can be used to select the associated phase set.

16.3.4.3. *Histogram of a Fourier synthesis*

The histogram of a Fourier synthesis $\rho(\mathbf{r})$ indicates which values are present and how frequently these values appear in the synthesis (Lunin, 1988, 1993; Harrison, 1988; Luzzati *et al.*, 1988; Zhang & Main, 1990). To present the histogram numerically, the interval $(\rho_{\min}, \rho_{\max})$ of the possible values of $\rho(\mathbf{r})$ is divided into K equal parts (bins) and for every bin the frequency

$$\nu_k = n_k/N, \quad k = 1, \ldots, K, \tag{16.3.4.1}$$

is calculated. Here, N is the total number of grid points at which $\rho(\mathbf{r})$ is calculated and n_k is the number of grid points with $\rho(\mathbf{r})$ values belonging to the kth bin. The set of frequencies $\{\nu_k\}_{k=1}^{K}$ is called the histogram corresponding to the function $\rho(\mathbf{r})$. It depends on the resolution of the synthesis and is sensitive to phase errors. The 'standard histogram' $\{\nu_k^{\rm exact}\}_{k=1}^{K}$ at a particular resolution corresponds to the Fourier synthesis calculated with the observed magnitudes and the correct phases. It can be predicted before the phases are determined (Zhang & Main, 1990; Lunin & Skovoroda, 1991). When the standard histogram is known, it can be used to select appropriate Fourier syntheses. For example, a selection criterion may be defined as the correlation of the standard histogram with that from the Fourier synthesis calculated with the observed magnitudes and trial phases. Similar low-resolution phasing ideas have been used in protein electron crystallography (Dorset, 2000).

16.3.4.4. *Map connectivity*

The quality of phase sets may be also judged by the topological properties of regions of high electron density, *e.g.* their connectivity. A visual inspection of continuous regions in Fourier maps and the absence of noisy peaks were used for many years to estimate map quality. A formal scheme of the use of connectivity for phase improvement was discussed by Baker *et al.* (1993).

These ideas can be incorporated into low-resolution phasing as follows (Lunin, Lunina & Urzhumtsev, 2000). For a Fourier synthesis, $\rho(\mathbf{r})$, calculated with the observed magnitudes and trial phases, each trial phase set is associated with a mask region

$$\Omega_\kappa = \{\mathbf{r}\colon \rho(\mathbf{r}) > \kappa\} \tag{16.3.4.2}$$

composed of the grid points with the highest values of $\rho(\mathbf{r})$. The simplest characteristics of the region are the number of connected components in the region Ω_κ and their size. If the synthesis resolution is low and the cutoff level is high enough, it is expected that the region Ω_κ will consist of a small number of globs corresponding to isolated molecules. The correspondence between the connected components in the Ω_κ mask and the desired number (for example, a known number of molecules in the unit cell) may be used as a connectivity-based selection criterion. More sophisticated criteria can be introduced.

16.3.4.5. Few-atoms model approach

At low resolution, the content of a macromolecular crystal may be represented by a set of large isotropic Gaussian scatterers (pseudo-atoms). The number of scatterers necessary for appropriate modelling depends on the molecular shape and the resolution. Their size, represented by their isotropic displacement parameter (B factor), can be estimated at the first step of the procedure. The coordinates of the spheres can be generated randomly and uniformly in the unit cell. For an advanced search, when the molecular envelope is already known, the spheres can only be generated inside this envelope. More complicated generation rules can be applied as well. For a generated model, a set of structure factors $\mathbf{F}^{\rm calc}(\mathbf{s})$ is calculated and their magnitudes $F^{\rm calc}(\mathbf{s})$ are compared with the experimental data $F^{\rm obs}(\mathbf{s})$ (Lunin *et al.*, 1995). When these values are close enough, the corresponding phase set is selected for further analysis.

In the simplest case, when the molecule is approximated by a single sphere, a systematic search (instead of a random one) of the position of this sphere in the unit cell becomes possible (Jack *et al.*, 1975; Podjarny *et al.*, 1987; Harris, 1995; Andersson & Hovmöller, 1996). On the other hand, some attempts to obtain *ab initio* molecular envelopes when working with many pseudo-atoms have been also reported (Subbiah, 1991, 1993; David & Subbiah, 1994).

16.3.4.6. Likelihood-based selection

Statistical likelihood estimates the probability of reproducing experimental values within a framework of a statistical hypothesis. For example, the likelihood of a trial mask region may be estimated as the probability of obtaining the values of the observed magnitudes when placing atoms randomly and uniformly into the mask and calculating the structure factors from such a random model (Lunin *et al.*, 1998):

$$L = \text{Probability}\big\{\{F^{\rm calc}(\mathbf{s})\}\text{ are close to }\{F^{\rm obs}(\mathbf{s})\}\big\},\quad \mathbf{s}\in S_{\rm test}. \tag{16.3.4.3}$$

The most reasonable masks are those with the highest probability. In an advanced approach, more general prior probability distributions $p_{\rm prior}(\mathbf{r})$ for atomic coordinates are considered, and a search for the one that maximizes the probability is conducted [equation (16.3.4.3)] (Bricogne & Gilmore, 1990). Such an approach may be used to select a mask (or prior) from several alternatives.

The likelihood given by equation (16.3.4.3) becomes a selection criterion for phase sets if every trial phase set is associated with a mask or more general prior. A mask may be constructed as a region of highest values in a Fourier synthesis calculated with observed magnitudes and trial phases (Petrova *et al.*, 2000). A more advanced prior distribution may be associated with trial phases. For example, a search for the most featureless distribution (maximum entropy) among all the distributions that are consistent with the trial phases and observed magnitudes has been proposed (Bricogne & Gilmore, 1990). The likelihood given by equation (16.3.4.3) may be calculated in a straightforward Monte Carlo-type procedure (Petrova *et al.*, 2000) or with the use of an analytical approximation of the likelihood function (Lunin & Urzhumtsev, 1984; Bricogne & Gilmore, 1990). It should be noted that the set of reflections $S_{\rm test}$ used to calculate the likelihood given by equation (16.3.4.3) is generally different from the set of reflections $S_{\rm work}$ for trial phases.

16.3.4.7. Binary functions

Binary integer programming (BIP) is an effective approach for solving a system of linear inequalities in binary unknowns (0 or 1). Crystallographers are often interested in the study of a region with density values above a certain level, *i.e.* in a binary function representing this region.

The unknown phase values are linked to the observed magnitudes by nonlinear equations, but the equations may be reduced to linear ones if the phase values are restricted to a grid (Lunin, Urzhumtsev & Bockmayr, 2002). On the other hand, the use of binary representations of electron density and phases introduces additional errors in the calculations, reducing the advantages of the BIP approach. Another approach for obtaining binary masks at a grid uses genetic algorithms (Webster & Hilgenfeld, 2001).

16.3.4.8. Common features of selection criteria

All the targets reported above (as well as some others tried in order to select phase sets) show similar problems when applied at low resolution (Lunin, Lunina, Petrova *et al.*, 2000):

(i) The best value of a target may correspond to quite a poor phase set.
(ii) The target value for a good phase set may be significantly worse than the best target value.
(iii) Local refinement of model parameters or phases may lead to significant improvement of the target value without any improvement in the phases.

Owing to these problems, attempts to find the solution of the low-resolution phase problem by minimizing (or maximizing) a target are unreliable. At the same time, the selection of phase sets from a random ensemble by an appropriate target significantly increases the fraction of good ones.

16.3.5. Processing of the output

The output of the selection procedure may be presented as a two-dimensional table. In this table, each column represents one selected phase set and each row corresponds to one structure factor, represented by the phase value in different selected phase sets. If a selected phase set is considered as a point in multi-dimensional configuration space of all phase sets, the output becomes a ‘cloud’ in this space. A definition of the distance between two points in this space is required to study the detail of the distribution of these points (see Section 16.3.5.5).

16.3.5.1. Formal comparison of phase sets

Most frequently, two quantities are used to compare phase sets. One is the mean phase error,

$$D_\varphi = \frac{1}{M}\sum_{\mathbf{s}\in\mathbf{S}} \left|\varphi_{\mathbf{1}}(\mathbf{s}) - \varphi_2(\mathbf{s})\right|, \tag{16.3.5.1}$$

which takes into account the phase values only. The second quantity is the map correlation coefficient (Lunin & Woolfson, 1993),

$$\begin{aligned} C_\varphi &= \frac{\int\left[\rho_1(\mathbf{r}) - \langle\rho_1\rangle\right]\left[\rho_2(\mathbf{r}) - \langle\rho_2\rangle\right]\,{\rm d}V_{\mathbf{r}}}{\left\{\int\left[\rho_1(\mathbf{r}) - \langle\rho_1\rangle\right]^2\,{\rm d}V_{\mathbf{r}}\,\int\left[\rho_2(\mathbf{r}) - \langle\rho_2\rangle\right]^2\,{\rm d}V_{\mathbf{r}}\right\}^{1/2}} \\ &= \frac{\sum_{\mathbf{s}\in S} F^{\rm obs}(\mathbf{s})^2\cos\left[\varphi_1(\mathbf{s}) - \varphi_2(\mathbf{s})\right]}{\sum_{\mathbf{s}\in S} F^{\rm obs}(\mathbf{s})^2}, \end{aligned} \tag{16.3.5.2}$$

which weighs the differences by structure-factor phases. Here, M is the number of reflections in the studied set S, $\varphi_1(\mathbf{s})$ and $\varphi_2(\mathbf{s})$ are phase values corresponding to reflection $\mathbf{s}$ in two phase sets, $\rho_1(\mathbf{r})$ and $\rho_2(\mathbf{r})$ are Fourier syntheses calculated using the observed magnitudes and phases to be compared, and the sums in reciprocal space are calculated without the $F(\mathbf{0})$ term. Each of these quantities has its own disadvantage. The first is influenced by a number of weak reflections with poor phases that do not strongly affect the Fourier map but do significantly increase the value of D_φ. On the other hand, C_φ is influenced mostly by a small number of very strong reflections and is not so sensitive to errors in the phases of other structure factors. Sometimes, additional weighting in equations (16.3.5.1) and (16.3.5.2) or statistical calculations in resolution shells are applied to attenuate these effects.

If a collection of phase sets is considered as a cloud in multi-dimensional space, a formal distance may be defined on the basis of equation (16.3.5.2) as

$$\begin{aligned} d_\varphi &= \left\{ \frac{\int \left[\rho_1(\mathbf{r}) - \rho_2(\mathbf{r})\right]^2 \,\mathrm{d}V_\mathbf{r}}{\int \left[\rho_1(\mathbf{r})\right]^2 \,\mathrm{d}V_\mathbf{r}} \right\}^{1/2} \\ &= \left\{ \frac{\int \left[\rho_1(\mathbf{r}) - \rho_2(\mathbf{r})\right]^2 \,\mathrm{d}V_\mathbf{r}}{\int \left[\rho_2(\mathbf{r})\right]^2 \,\mathrm{d}V_\mathbf{r}} \right\}^{1/2} \\ &= \left[2\left(1 - C_\varphi\right)\right]^{1/2}, \end{aligned} \qquad (16.3.5.3)$$

varying from 0 to 2.

These formal measures of closeness are convenient when comparing phase sets with small differences but may be misleading at the initial stages of *ab initio* phasing, as discussed below.

16.3.5.2. *Phase ambiguity and alignment of phase sets*

Two randomly generated phase sets may result in Fourier maps $\rho_1(\mathbf{r})$ and $\rho_2(\mathbf{r})$ that differ only by an origin shift $\mathbf{t}$ permitted for the given space group: $\rho_2(\mathbf{r}) = \rho_1(\mathbf{r} - \mathbf{t})$. These two maps present the same object, they are calculated with the same experimental magnitudes and they are indistinguishable by the criteria discussed above. Therefore, they could both appear in the output of the selection procedure. However, the corresponding phases in these phase sets are different,

$$\varphi_2(\mathbf{s}) = \varphi_1(\mathbf{s}) + 2\pi(\mathbf{s}, \mathbf{t}), \qquad (16.3.5.4)$$

and an attempt to average such phase sets or superpose the corresponding maps is wrong. To compare and average these phase sets correctly they (or the corresponding maps) should be aligned (Lunin *et al.*, 1990; Hašek & Schenk, 1992; Lunin & Lunina, 1996). This alignment may be done on the basis of any formal measure of phase closeness, for example equations (16.3.5.1) or (16.3.5.2). It searches for the space-group-permitted shift of the second synthesis that results in the smallest phase difference between the two sets.

The enantiomer density transformation $\rho(\mathbf{r}) \to \rho(-\mathbf{r})$ conserves the features of the Fourier maps used in the selection criteria, conserves the magnitudes of the structure factors and substitutes the phases φ by $-\varphi$. Only high-resolution images might be able to solve the ambiguity and reveal the 'handedness' at later steps through the features of the secondary-structure elements. At the initial stage of phasing, the two enantiomer solutions may be considered equivalent and the enantiomer change $\varphi \to -\varphi$ may be added as an allowed operation in the alignment process.

Finally, a density transformation $\rho(\mathbf{r}) \to -\rho(\mathbf{r})$ preserves the magnitudes, changes the phases by π and flips the envelopes for a given cutoff level. In order to assess which of the two molecular envelopes is more probable, $\rho(\mathbf{r})$ or $-\rho(\mathbf{r})$, a generalized maximum-likelihood technique can be used (Lunin *et al.*, 1998).

The problem of phase alignment may be solved to some extent by fixing in advance the phase values for a small number (up to four, depending on the space group) of specially chosen reflections (reflections fixing the origin and/or the enantiomer). Nevertheless, for large phase sets the influence of these reflections may be too small to produce a reliable alignment.

In the following, when we discuss the closeness of two phase sets, we always suppose that they have already been aligned.

16.3.5.3. *Multiple alignment and 'central' phase set*

The problem of alignment becomes more complicated when applied to several phase sets simultaneously. The choice of a 'central' point of reference seems to be a reasonable solution, provided it minimizes the dispersion of the phase sets. To do so, let $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N\}$ be a 'cloud' of selected phase sets considered as points in multidimensional configuration space. The point $\mathbf{v}^*$ is defined as the centre of the cloud if it minimizes the size of the cloud after all phase sets have been aligned to it:

$$Q(\mathbf{v}^*) = \sum_{n=1}^{N} d_\varphi^2(\mathbf{v}_n, \mathbf{v}^*) \Rightarrow \min, \qquad \mathbf{v}^* \in \{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N\}, \qquad (16.3.5.5)$$

or

$$Q_1(\mathbf{v}^*) = \sum_{n=1}^{N} d_\varphi(\mathbf{v}_n, \mathbf{v}^*) \Rightarrow \min. \qquad (16.3.5.6)$$

This phase set may be used as the reference point to align the phase sets or as a current solution of the phase problem.

16.3.5.4. *Phase averaging and assignment of the probability distribution*

The simplest way to process the selected phase sets is to average them. For every reflection $\mathbf{s}$ from the set S, the best phase $\varphi^{\text{best}}(\mathbf{s})$ and its figure of merit $m(\mathbf{s})$ are calculated as

$$m(\mathbf{s}) \exp\left[i\varphi^{\text{best}}(\mathbf{s})\right] = \frac{1}{N} \sum_{n=1}^{N} \exp\left[i\varphi_n(\mathbf{s})\right], \qquad (16.3.5.7)$$

where $\varphi_n(\mathbf{s})$ is the phase in the nth selected set corresponding to the reflection $\mathbf{s}$, and N is the number of selected sets. The figure of merit

$$m(\mathbf{s}) = \frac{1}{N} \sum_{n=1}^{N} \cos\left[\varphi_n(\mathbf{s}) - \varphi^{\text{best}}(\mathbf{s})\right] \qquad (16.3.5.8)$$

reflects the divergence of the phase values of the reflection $\mathbf{s}$ in different selected phase sets.

The output of the phasing cycle may also be used to derive an approximate unimodal distribution,

$$\begin{aligned} P(\varphi) &= \frac{1}{I_0(T)} \exp[T \cos(\varphi - \theta)] \\ &= \Omega(A, B) \exp[A \cos\varphi + B \sin\varphi], \end{aligned} \qquad (16.3.5.9)$$

(also called 'von Mises', 'circular normal', 'Sim' *etc.*), with $\theta = \varphi^{\text{best}}$, $I_1(T)/I_0(T) = m$, or a bimodal distribution,

$$P(\varphi) = \Omega(A, B, C, D) \times \exp[A\cos\varphi + B\sin\varphi + C\cos 2\varphi + D\sin 2\varphi] \qquad (16.3.5.10)$$

(Hendrickson & Lattman, 1970). These distributions may be used to generate phases at the next cycle of phasing.

16.3.5.5. Cluster analysis

Accurate processing of the selected phase sets may involve methods of cluster analysis (Lunin *et al.*, 1990, 1995; Buehler *et al.*, 2009). Cluster analysis is a branch of applied mathematics aimed at classifying a set of points in a multidimensional space into several compact groups called clusters (or classes), so that the points inside a particular cluster are close to each other while different clusters are distant in space. Methods of cluster analysis use the matrix of point-to-point distances as input information. If the cluster analysis shows that the selected population can be split into several significantly different clusters, then the averaging is performed in each cluster separately, resulting in several alternatives for the solution of the phase problem and requiring multisolution strategies.

16.3.6. Conclusions and examples

The study of large complexes has renewed research interest in low-resolution phasing, since the corresponding crystals often diffract only to low resolution. *Ab initio* low-resolution phasing can give shape information in the unit cell and, in favourable cases, secondary-structure information. This information can be combined with other imaging techniques to obtain a reliable description of the structure.

The low-resolution maps for the ribosomal T50S particle obtained as early as the mid-1990s (Volkmann *et al.*, 1995; Urzhumtsev *et al.*, 1996; see also Lunin, Lunina *et al.*, 2002), for the low-density lipoprotein particle (Lunin *et al.*, 2001) and for some smaller macromolecules (Fokine *et al.*, 2003; Müller *et al.*, 2006) are some examples. In favourable cases, such images show not only the molecular envelope but also the secondary structure (Lunina *et al.*, 2003). At the same time, the current *ab initio* low-resolution phasing procedures are not yet completely automated and require significant human intervention.

PART 17. MODEL BUILDING AND COMPUTER GRAPHICS

Chapter 17.1. Macromolecular model building and validation using *Coot*

P. Emsley, B. Lohkamp and K. Cowtan

17.1.1. Introduction

Macromolecular model building using X-ray data is to some extent an interactive task, involving the iterative application of various optimization algorithms with the evaluation of the model and interpretation of the electron density by the scientist. *Coot* is an interactive three-dimensional molecular-modelling program particularly designed for building and validation of protein structures by facilitating the steps of the process.

In recent years, the initial construction of the protein chain has often been carried out using automatic model-building tools such as *ARP/wARP* (Langer *et al.*, 2008), *SOLVE/RESOLVE* (Wang *et al.*, 2004) and more recently *Buccaneer* (Cowtan, 2006). Therefore, relatively more time and emphasis has been placed on model validation than had previously been the case (Dauter, 2006). The refinement and validation steps become increasingly important and also more time consuming as data sets become poorer. *Coot* aims to provide convenient access to as many of the tools required in the iterative refinement and validation of a macromolecular structure as possible, to facilitate those aspects of the process which cannot be performed automatically. The software is also designed with a goal of being easy to learn, in order to provide a low barrier for scientists who are beginning to work with X-ray data (Fig. 17.1.1.1).

The principal tasks of the software are the visualization of macromolecular structures and data, the building of models into electron density, and the validation of existing models; these will be considered in the next three sections. The remaining sections of the chapter will deal with more technical aspects of the software, including interactions with external software, scripting and testing.

Figure 17.1.1.1
The *Coot* main window. The main display area shows a molecule and electron density. At the top of the window is a menu bar providing access to most of the tools. Commonly used model-manipulation tools are also available through the toolbar on the right. Below the menu bar is an area for user-definable buttons.

17.1.2. Model building

Initial building of protein structures from experimental phasing is usually accomplished by automated methods. The main focus in *Coot*, therefore, is the completion of initial models generated by either molecular replacement or automated model building. However, the following features are provided for cases where an initial model is not available.

17.1.2.1. Tools for general model building

17.1.2.1.1. Cα baton mode

Baton building, introduced by Jones [see for example Kleywegt & Jones (1994)] allows a protein main chain to be built by using a 3.8 Å 'baton' to position successive α-carbons at the correct spacing. In *Coot*, this facility is reproduced and coupled with an electron-density ridge-trace skeleton (Greer, 1974). First, a skeleton is calculated following the ridges of the electron density. Then, the user selects baton-building mode, which places an initial baton with one end at the current screen centre. Candidate positions for the next α-carbon are highlighted as crosses, selected from those points on the skeleton which lie at the correct distance from the start point. The user can cycle through a list of candidate positions using the 'Try Another' button, or, alternatively, rotate the baton freely by use of the mouse. Additionally, the length of the baton can be changed to accommodate moderate inaccuracies in the α-carbon positions. Once a new position is accepted, the baton moves so that its base is on the new α-carbon. In this way, a chain may be traced manually at a rate of between 1 and 10 residues per minute.

Having placed the α-carbons, the rest of the main-chain atoms may be generated automatically using an implementation of the method of *CALPHA* (Esnouf, 1997).

17.1.2.1.2. Find secondary structure

Protein secondary-structure elements, including α-helices and β-strands, can be located by their repeating electron-density features, which lead to high and low electron-density values in characteristic positions relative to the consecutive α-carbons. The 'Find Secondary Structure' tool performs a six-dimensional rotational and translational search to find the likely positions of helical and strand elements within the electron density. This search has been highly optimized in order to achieve interactive performance for moderately sized structures, and, as a result, is less exhaustive than the corresponding tools employed in the automated model-building packages. However, it can provide a

Copyright © 2012 International Union of Crystallography

very rapid indication of map quality and a starting point for model building.

17.1.2.1.3. *Place helix here* and *Place strand here*

At low resolution it is sometimes possible to identify secondary-structure features in the electron density when the Cα positions are not obvious. If the user can identify that a helix or strand feature is present at a position in the electron-density map, *Coot* can place that feature automatically. This involves several stages. First, the orientation of the helix or strand is identified by using a rotational search to orient a cylindrical template to contain the maximum amount of density. Then, an ensemble of helix or strand fragments is placed in the density to determine the direction and registration of the helix or strand. The best fragment is extended to provide the longest element with a good match to the density.

17.1.2.1.4. *Find ligands*

The ability to fit ligands rapidly into electron-density maps is a frequently used technique, particularly useful to pharmaceutical companies (*e.g.* Williams *et al.*, 2005). The mechanism in *Coot* addresses a number of ligand-fitting scenarios and is a modified form of an algorithm described previously (Oldfield, 2001). It is common practice in 'fragment screening' to soak different ligand types into the same crystal (*e.g.* Blundell *et al.*, 2002). Using *Coot*, one can either specify a region in space or search a whole map for either a single or a number of different ligand types. In the 'whole map' scenario, candidate ligand sites are found by cluster analysis of a residual map and the candidate ligands are fitted in turn to each site, the candidate orientations being generated by matching the eigenvectors of the ligand to that of the cluster. Each candidate ligand is fitted and scored against the electron density. The best fitting orientation of the ligand candidates is chosen.

17.1.2.2. Rebuilding and refinement

The rebuilding and refinement tools are the primary means of model manipulation in *Coot*, and are all grouped together in the 'Model/Fit/Refine' tool set. These tools may be accessed either through a toolbar which is usually docked on the right-hand side of the main window, or through a separate 'Model/Fit/Refine' window containing buttons for each of the toolbar functions.

The core of the rebuilding and refinement tools is the real-space refinement (RSR) engine, which handles refinement of the atomic model against an electron-density map and regularization of the atomic model against geometric restraints. Refinement may be invoked both interactively when executed by the user, and non-interactively as part of some of the automated fitting tools. The refinement and regularization tools are supplemented by a range of additional tools aimed at assisting the fitting of protein chains. These features are discussed below.

17.1.2.3. Tools for moving existing atoms

17.1.2.3.1. Real-space refine zone

The real-space refine tool is the most frequently used tool in the refinement and rebuilding of atomic models, and is also incorporated as a final stage in a number of other tools, *e.g.* 'Add Terminal Residue . . . '. In interactive mode, the user selects the RSR button and then two atoms bounding a range of monomers (amino acids or otherwise). All atoms in the selected range of monomers will be refined, including any flanking residues. Atoms of the flanking residues are marked as 'fixed' but are required to be added to the refinement so that the geometry (*e.g.* peptide bonds, angles and planes) between fixed and moving parts is also optimized.

The selected atoms are refined to optimize a target consisting of two terms: the first being the Z-weighted sum of the electron-density values over all the atomic centres and the second being the stereochemical restraints on bond lengths, angles *etc*. The progress of the refinement is shown with a new set of atoms, displayed in white/pale colours. Once convergence is reached, the user is offered a dialogue box with a set of r.m.s. deviation scores and coloured 'traffic lights' indicating the current geometry scores in each of the geometrical criteria. Additionally, a warning is issued if the refined range contains new *cis*-peptide bonds.

The user may adjust the model by selecting an atom with the mouse and dragging it. The other atoms will move with the dragged atoms. Alternatively, a single atom may be dragged by holding the Ctrl key. As soon as the atoms are released, the model will refine from the dragged position. Additional atoms may be selected to be fixed during the refinement. This selection is made before starting the refinement.

17.1.2.3.2. Sphere refinement

One problem with the refinement mode described above was that it only considers a linear range of residues. This can cause problems, particularly at lower resolutions with some side chains inappropriately falling into electron density of neighbouring residues. Additionally, a linear residue selection precluded the refinement of entities such as disulfide bonds. Therefore, a new residue-selection mechanism was introduced to address these issues: the so called 'Sphere Refinement'. This mode selected residues that have atoms within a given radius of a specified position (typically within 4 Å of the centre of the screen). The residues are pairwise matched against the dictionary to find the appropriate restraint type.

17.1.2.3.3. Ramachandran restraints

At lower resolutions it is sometimes difficult to obtain an acceptable fit to the density and at the same time produce a Ramachandran plot of high quality (most residues in favourable regions and less than 1% outliers). If a Ramachandran score is added to the target function then the Ramachandran plot can be improved.

The analytical form for torsion gradients ($\partial\theta/\partial x_1$ and so on) for each of the x, y, z positions of four atoms contributing to the torsion angle has been reported previously (Emsley & Cowtan, 2004) (in the case of Ramachandran restraints, the θ torsions will be φ and ψ). The extension of the torsion gradients for use in Ramachandran restraints is performed using a two-dimensional log Ramachdran plot. This is generated as tables (one for each type of Pro, Gly and non-Pro or Gly), containing the log of the Ramachandran distribution. Where the Ramachandran probability goes to zero, the log probability would become infinite, and so is replaced by values which become increasingly negative with distance from the nearest nonzero value. This provides a weak gradient in the disallowed regions towards the nearest allowed region.

17.1.2.3.4. Rotamer tools

Four tools are available for the fitting of protein side chains. For a side chain whose amino-acid type is already correctly assigned, the best rotamer may be chosen to fit the density either automatically or manually. If the automatic option is chosen, then the side-chain rotamer from the *MolProbity* library (Lovell *et al.*,

2000) that gives rise to the highest density values at the atomic centres is selected and refined. Otherwise, the user is presented with a list of rotamers for that side-chain type, sorted by frequency in the database. Rotamers are named according to the *MolProbity* system (Lovell *et al.*, 2000).

The other two options, ‘Mutate & Auto Fit’ and ‘Simple Mutate’, allow the amino-acid type to be assigned or changed. The ‘Mutate & Auto Fit Rotamer’ option allows an amino-acid type to be selected from a list and then immediately performs the autofit rotamer operation as above. The ‘Simple Mutate’ option changes the amino-acid type and builds the side-chain atoms in the most frequently occurring rotamer, without refinement.

17.1.2.3.5. *Torsion editing*

Side-chain (or ligand) torsion angles need to be defined prior to editing. Either the user manually defines the four atoms forming the torsion angle (‘Torsion General’) or the torsion angles are determined from a dictionary description and the user selects the one to edit. In the latter case, the bond around which the selected torsion angle is edited is visually marked.

17.1.2.4. *Tools for adding atoms to the model*

17.1.2.4.1. *Find waters*

The water-finding mechanism in *Coot* uses the same mechanism for detecting unmodelled density as is used in the ligand fitting. However, only those features below a certain volume (by default 4.2 Å^3) are considered as candidate sites for water molecules. The centre of each feature is computed and then a distance check is made to the potential hydrogen-bond donors or acceptors in the protein molecule (or other waters). The distance criteria for an acceptable hydrogen-bond length is under user control. Additionally, a test for acceptable sphericity of the electron density is performed.

17.1.2.4.2. *Add terminal residue*

The *MolProbity* φ, ψ distribution is used to generate a set of randomly selected φ, ψ pairs. These random angles are used to generate the position of the N, Cα, O and C atoms of the next two residues. The conformation of these new atoms is then scored against the electron-density map and recorded. This procedure is carried out a number of times. The best-fitting conformation is offered as a candidate to the user (only the nearest of the two residues is kept).

17.1.2.5. *Tools for handling noncrystallographic symmetry (NCS)*

Noncrystallographic symmetry (NCS) can be exploited during the building of an atomic model, and also in the analysis of an existing model. In addition to some specific validation tools, *Coot* provides five tools to help with the building and visualization of NCS-related molecules:

(i) NCS ghost molecules. In order to visualize the similarities and differences between NCS-related molecules, a ‘ghost’ copy of any or all NCS-related chains may be superimposed over a chain in the model. The ‘ghost’ copies are displayed in thin lines and coloured differently as well as uniformly in order to distinguish them from the original. The superposition may be performed automatically by secondary-structure matching (Krissinel & Henrick, 2004), or by least-squares superposition.

(ii) NCS-averaged maps. In addition to viewing NCS-related copies of the electron density, the average density of the related regions may be computed and viewed. In noisy maps, this may provide a clearer starting point for model building.

(iii) NCS rebuilding. When building an atomic model of a molecule with NCS, it is often more convenient to work on one chain and then replicate the changes made to every NCS-related copy of that chain (at least in the early stages of model building).

(iv) NCS ‘jumping’: The view centre jumps to the next NCS-related peer chain and, at the same time, the NCS operators are taken into account so that the relative view remains the same. This provides a means for rapid visual comparison of NCS-related entities.

17.1.3. Validation

Coot incorporates a range of validation tools, including generic validation of the model against density, comprehensive geometrical validation tools for protein structures and additional validation tools specific to nucleotides. It also provides convenient interfaces to external validation tools, most notably the *MolProbity* suite (Davis *et al.*, 2007; Chapter 21.6), but also to the *Refmac* refinement software (Murshudov *et al.*, 1997) and dictionary (Vagin *et al.*, 2004).

Many of the internal validation tools provide a uniform interface in the form of colour-coded bar charts, for example the ‘Density fit analysis’ chart (Fig. 17.1.3.1). This window contains one bar chart for each chain in the structure. Each chart contains one bar for each residue in the chain. The height and colour of the bar both indicate the ‘goodness’ of the monomer, with small green bars being good or expected/conventional and large red bars being bad or unconventional. The chart is active, *i.e.* on mousing over the bar, tooltips provide relevant statistics, and clicking on a bar changes the view in the main graphics window to centre on the selected residue. In this way, a rapid overview of model quality is obtained and problem areas can be easily accessed. In order to obtain a good structure for submission, the user may simply cycle though the validation options, correcting any problems found.

The available validation tools are described in more detail in the following sections.

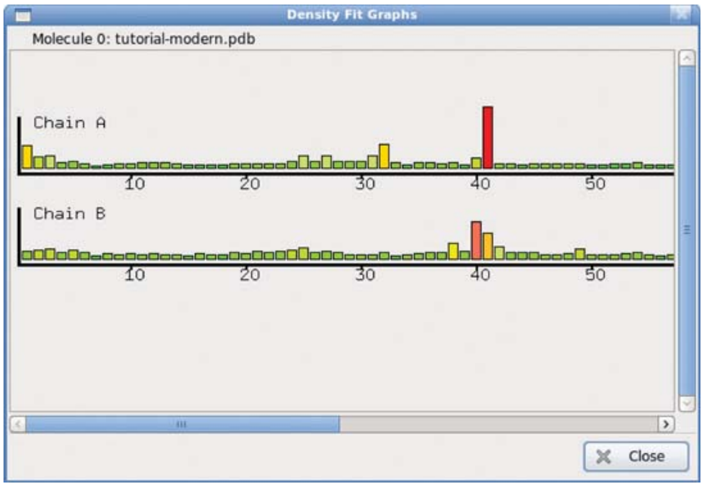

Figure 17.1.3.1
A typical validation graph. Bars represent individual residues in a chain, with an indication of quality for that residue given by both size and colour. The plot is interactive, *i.e.* clicking on a bar takes the user to the corresponding residue in the main window.

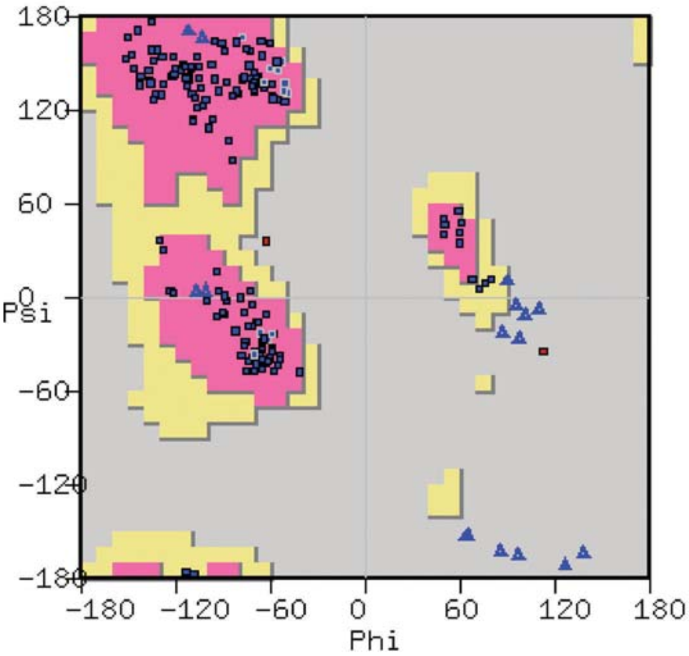

Figure 17.1.3.2
Interactive Ramachandran plot. The axes show the φ and ψ angles. Preferred regions are coloured in pink, allowed regions in yellow, and the background in grey for disallowed regions. Standard residues are shown as dark-blue squares, Pro residues as light-blue squares and Gly residues as light-blue open triangles. Residues in the disallowed regions are coloured red. Below the graph, in the *Coot* dialogue box, a summary of the number (and percentages) of residues in the different regions of the Ramachandran plot is given.

17.1.3.1. Ramachandran plot

The Ramachandran plot tool (Fig. 17.1.3.2) launches a new window in which the Ramachandran plot for the active molecule is displayed. A data point appears in this plot for each residue in the protein, with different symbols distinguishing Gly and Pro residues. The background of the plot shows frequency data for Ramachandran angles using the Richardsons' data (Lovell *et al.*, 2003).

The plot is interactive: clicking on a data point moves the view in the three-dimensional canvas to centre on the corresponding residue. Similarly, selecting an atom in the model highlights the corresponding data point. Moving the mouse over a data point corresponding to a Gly or Pro residue causes the Ramachandran frequency data for that residue type to be displayed.

17.1.3.2. Geometry analysis

The geometry (bonds, angles, planes) for each residue in the selected molecule is compared to dictionary values (typically provided by the mmCIF *Refmac* dictionary). Torsion angles are not analysed (there are other validation tools for torsion angles).

The statistics for the geometry graph are the average Z value for each of the geometry terms for that residue (peptide geometry distortion is shared between neighbouring residues). The tooltip on the geometry graph describes the geometry features giving rise to the highest Z value.

17.1.3.3. Peptide ω analysis

This validation tool for peptide ω torsion angles produces a graph marking the deviation from 180 degrees of the peptide ω angle. The deviation is assigned to the residue to include the C and O atoms of the peptide link. Thus, peptide ω angles of 90° are very bad. Optionally, ω angles of 0° can be considered ideal (for the case of intentional *cis*-peptide bonds).

17.1.3.4. Rotamer analysis

The rotamer statistics are generated from the nearest conformation in the *MolProbity* rotamer probability distribution (Lovell *et al.*, 2000). The height of the bar is inversely proportional to the rotamer probability.

17.1.3.5. Density-fit analysis

The bars in the density-fit graphs are inversely proportional to the average Z-weighted electron density at the atom centres and to the grid sampling of the map (*i.e.* maps with coarser grid sampling will have lower bars than a more finely gridded map, all other things being equal). Accounting for the grid sampling allows lower-resolution maps to have a density-fit graph without many or most residues being marked as worrisome owing to their atoms being in generally low levels of density.

17.1.4. Scripting

Many internal functions in *Coot* are accessible *via* an automically generated (SWIG) interface to the scripting languages Python (http://www.python.org) and Guile (a scheme interpreter; Kelsey *et al.*, 1998; http://www.gnu.org/software/guile/guile.html). Some of *Coot*'s graphics widgets are available for scripting *via* the same interface.

17.1.5. Discussion

Coot combines a range of modern methods in macromolecular model building and validation with a modern graphical user interface, following current design conventions to achieve ease of use, productivity, aesthetics and forgiveness. This is an ongoing process and although improvements can still be made, we believe that *Coot* provides a shallow learning curve combined with a high level of crystallographic awareness to aid the novice and non-specialist user, while providing a powerful and configurable tool set for the expert.

Chapter 17.2. Molecular graphics and animation

A. J. Olson

17.2.1. Introduction

Visualizing the unseeable world of molecules is the fundamental goal of crystallographic structure determination. Thus there is a natural synergy between the science of unravelling molecular structure and the technology of representing it. Graphics have always had a significant role in the analysis of diffraction data, the synthesis of molecular models and the communication of the information and knowledge gained in these scientific pursuits. At least since the time of René Häuy in the 18th century, crystallographers have attempted to use graphics and physical models to understand and explain the underlying nature of the solid state (Fig. 17.2.1.1). Over the years, crystallography has pushed the development of new technologies to aid in structure solution, and crystallographers have been early adaptors of new technologies. No technology has had more impact on crystallography than electronic computing. Nowhere is that impact more apparent than in what we have been able to study and how we have been able to visualize our structural results. With the pervasiveness of three-dimensional computer graphics in many aspects of everyday life, it is easy to forget the role that X-ray crystallography has played in its genesis and the role that graphics technology continues to play in the advancement of molecular structure analysis.

The human genome project and other efforts in biology and medicine have produced heightened emphasis on molecular depictions of increasing complexity. Visualization of such systems through computer-graphics technology is a key component in our understanding of these data and the models that we use to explain them. In fact, modelling and visualization techniques provide a bridge between experimental data at different scales, enabling placement of detailed atomic models of molecules from crystallography into lower-resolution data on large assemblies from electron microscopy or scanning probe imaging.

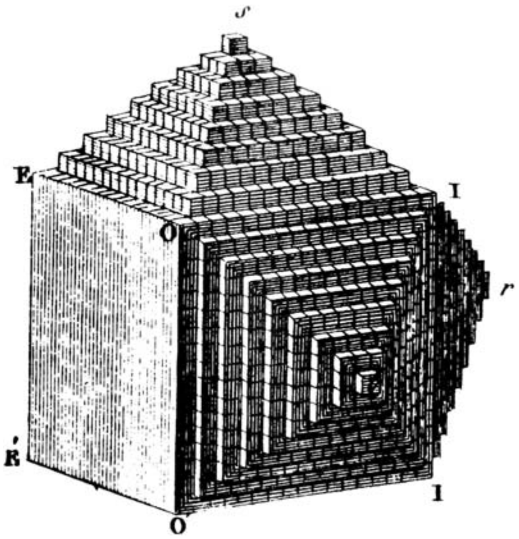

Figure 17.2.1.1
Model of a crystal structure proposed by René Häuy in *Traite elementaire de Physique*, Vol. 1 [Paris: De L'Imprimerie de Delance et Lesueur, 1803]. This model, proposed in 1784, was the first to connect the external facets of a crystal with an underlying regular arrangement of building blocks.

17.2.2. Background – the evolution of molecular graphics hardware and software

The complexity of molecular structure and the fact that these sub-microscopic objects of study are not directly visible have necessitated the use of physical or pictorial representations to aid in interpretation, manipulation and understanding. Illustrations and models made of wood, plastic or metal served these purposes from the development of the original theories of molecular structure through to the first nucleic acid and protein structures solved in the 1950s. Over the following years, computer graphics has evolved into a significant and ubiquitous technology, helping to sustain the explosive growth of macromolecular structure research. Today, computer graphics pervade the activities of much molecule-based research, from quantum chemistry to molecular biology.

Computer-based molecular graphics can be traced back to 1948 and the X-RAC project of R. Pepinsky at Pennsylvania State University (Pepinsky, 1952). Pepinsky developed an analogue computer to carry out the Fourier transformation of X-ray structure factors to produce electron-density maps. Integrated within X-RAC was an oscilloscope that could display the contours of the electron density (Fig. 17.2.2.1). These displays were, to my knowledge, the first computer-generated images of molecular structure. Crystallographers from around the world came to Pennsylvania State University to use X-RAC and to marvel at the speed and automation possible in the solution of molecular structures. While the digital revolution quickly overtook the analogue approach, X-RAC clearly set the precedent for molecular scientists as early implementors and adaptors of computational and graphics technology.

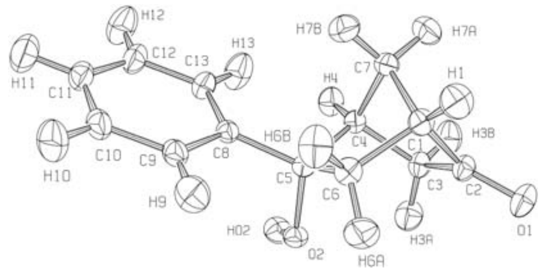

Figure 17.2.3.1
ORTEP plot of phenylhydroxynorbornanone showing atomic thermal ellipsoids (from *Thermal ellipsoid analysis: the fossil footprints of restless atoms*, by Carroll K. Johnson and Michael N. Burnett, Buerger Award Lecture at the ACA meeting in St. Louis, July 20–26, 1997).

In the 1960s, two seminal projects laid the foundation for modern molecular graphics. Early in the decade, Johnson's *ORTEP* (Johnson, 1970) program became widely available, allowing crystallographers to produce illustrations of three-dimensional (3-D) molecular structures on a pen plotter. These black-and-white line drawings of ball-and-stick models were used both for working drawings during structure analysis and for creating illustrations for publication. A few years later, experiments lead by Levinthal under Project MAC (Levinthal, 1966) at MIT pioneered the interactive display and transformation of 3-D molecular structures on a computer screen. By the end of the decade, the groundwork for molecular graphics was set: *ORTEP* convincingly demonstrated to a large number of scientists that the computer could be used as an alternative to the human hand to produce accurate drawings and stereoscopic pairs for the analysis and communication of the results of structural research. Project MAC showed that the computer could be used as an interactive environment in which to model and simulate on the molecular scale. These two projects helped define the two broad functions of molecular graphics: publication graphics, for which clarity of presentation is the essential goal, and working graphics, for which rapid feedback and high interactivity are the key elements.

In the 1970s, 3-D interactive computer-graphics systems became commercially available. Hardware offerings from companies such as Evans and Sutherland, Vector General, and Adage prompted a number of laboratories to develop interactive molecular-modelling software. Several of these early systems were devoted to the task of building an atomic model of a protein into the crystallographically derived electron-density map. Programs such as *BILDER* (Diamond, 1982), *MMSX* (Barry & McAlister, 1982), *FRODO* (Jones, 1978) and *GRIP* (Wright, 1982) began to replace metal Kendrew models and the cumbersome 'Richards Box' optical comparitors. This application, more than any other, sold these expensive (>$100 000) monochrome line-drawing graphics devices to the molecular-research community. Moreover, during that time, biomolecular structure determination was a major civilian consumer of 3-D interactive graphics devices.

Technical, commercial and scientific advances in the 1980s prompted enormous growth in the use of molecular graphics. As late as 1983, a worldwide list of laboratories using high performance graphics computers for molecular work could be maintained – the number was below 100 (Olson, 1983). By the end of the decade, that number grew into the thousands, and utilization spread beyond any ability to track it. At the beginning of the decade the expensive vector-graphics terminals were the only way to achieve interactive 3-D display. Ten years later, the colour raster display had taken over the interactive computer-graphics market, driving prices down and broadening display capabilities from lines and dots to include shaded surface representation. Early in the 1980s, several academic software packages, such as *GRAMPS/GRANNY* (O'Donnell & Olson, 1981; Connolly & Olson, 1985), *MIDAS* (Ferrin *et al.*, 1988) and *HYDRA* (Hubbard, 1986), went beyond electron-density fitting to provide general graphics functionality for examining molecular structure and properties. Over the decade, the remarkable evolution of computer hardware – the advent of microprocessors, very large scale integration (VLSI) devices, personal computers and scientific workstations – increased the accessibility of molecular graphics. By the mid-1980s, the demand was such that several commercial companies had been established to market molecular graphics and modelling software. By the end of the decade, structural scientists in academic and industrial research settings had a wide variety of use-tested hardware and software platforms with which to perform molecular modelling.

The 1990s witnessed remarkable advances in the technology and sociology of computing as well as in the science of molecular structure and design. Moore's law of the microcosm, which estimates that 'the effectiveness of microprocessors doubles every 18 months', continued to track growth accurately. Thus the performance-to-cost ratio of late 1990s computers was a millionfold higher than those of the mid-1960s. A 1997 200 Nintendo-64 game machine was faster and had more memory and far superior graphics than the Control Data 6600 supercomputer and peripherals of the 1960s, and, with its optional ($70) disk, bettered almost every technical specification of a 1980 VAX 11/780. Gelder's law of the telecosm posited in 1993 that 'bandwidth will treble every year for at least the next 25 years'. This, coupled with Metcalf's law, that 'the total value of a network to its users grows as the square of the total number of users' implies that the 'teleputer', or non-localized computing, is becoming the computational environment of the future.

While software development continues to lag behind hardware growth, the emergence of the World Wide Web and the concepts of network-based computing have catalysed a rethinking of the nature of software, its development, distribution and inter-operability. The concepts of cyberspace and 'virtual reality' have been implanted into the minds and expectations of the general public, promoting a renaissance in user-interface exploration and development. It is transforming the computer from a window through which to look into a portal through which to step. Suddenly, the other senses – sound, touch, taste and smell – can become part of the computational experience.

17.2.3. Representation and visualization of molecular data and models

In the early days of molecular computer graphics, the major goal was to represent the spatial structures of molecules, principally the locations of the atom centres and the covalent connectivity between them. Using X-ray diffraction analysis, one would first plot the electron density as line contours projected onto a plane and locate the atom centres from multiple projections. The molecule would then be represented by a simple bond diagram. As experimental and computational methods advanced, other representations were used to convey additional information about the structure. Johnson's *ORTEP* program plotted the thermal ellipsoids of each of the atoms, visualizing the magnitude and direction of their thermal vibrations as derived from the anisotropic temperature factors (Fig. 17.2.3.1). As colour raster

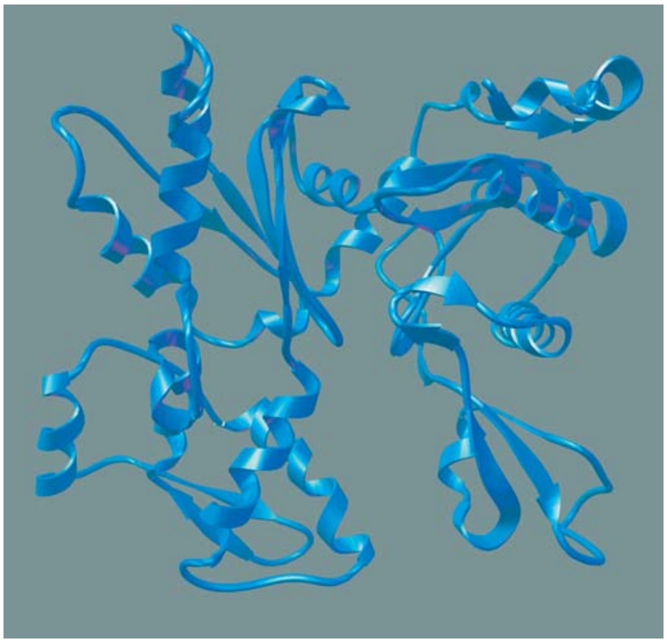

Figure 17.2.3.2
Ribbon diagram of actin monomer (PDB code: 1atn) (Kabsch *et al.*, 1990).

displays became available, space-filling CPK representations were used to visualize molecular shape and volume while using an atom-based colour scheme to show atomic composition and distribution (Porter, 1979) (see Fig. 17.2.3.4). The complexity of protein molecules prompted the introduction of simplified representations that replaced the all-atom visualization with tubes or ribbons (Branden *et al.*, 1975; Carson, 1991) (Fig. 17.2.3.2) that represented the fold of the protein chain. This simplification allowed the comparison of protein folds, and led to the beautiful classification of protein motifs by Richardson (1981).

As more structural information has become available, and as computational hardware technology has advanced, the ability to visualize a variety of molecular properties has become possible. Meanwhile, issues of interactivity, intelligibility and interpretability have become increasingly important as the systems under study have become more complex. There are three general approaches to visualizing the structures, properties and relationships of molecular systems: geometric construction, direct volumetric rendering and generic information visualization. Today almost all macromolecular modelling and visualization work is done using geometric representations of bonds, ribbons and surfaces, which are annotated by colour to represent atom type, chain characteristics, or electrostatic potential. For these purposes, there are several 'turn-key' programs that facilitate display and interaction. Programs such as *RASMOL* (Sayle & Milner-White, 1995), *GRASP* (Nichols *et al.*, 1995) and *MOLSCRIPT* (Kraulis, 1991) are widely used by the molecular-structure community. Some of the fundamentals of representation used in these types of programs, as well as more exploratory techniques, are described below.

While the world is continuous, our measurements of it tend to be finite and sampled. Thus data are usually represented as discrete values on a line, plane, volume or hypervolume. On the other hand, in order to capture the nature of the world, our models tend to be represented as continuous functions. Geometric construction is useful for rendering continuous models, while other techniques, such as volume rendering, lend themselves to the visualization of discrete data.

17.2.3.1. *Geometric representation*

Geometric construction encompasses dots, lines and surfaces described by lists of three-dimensional coordinates and connectivity or by analytic or parametric expressions that can generate such information for rendering. Basically, geometric rendering involves a projection of the 3-D geometry onto a two-dimensional viewing plane using matrix transformations that account for the viewpoint, perspective and clipping within the viewing volume. For dots and lines, the computation may end there; the only depth information in the rendering might be geometric perspective. Additional depth information can be added by 'atmospheric perspective' or depth cueing, where the brightness or colour is modulated by the depth values of the points (Fig. 17.2.3.3). Surface representations permit additional three-dimensional cues such as occlusion and shape-from-shading. Occlusion, or 'hidden surface removal', and atmospheric perspective depend on maintaining depth information for all of the picture elements (pixels) in screen space. Such 'depth-buffer' algorithms provide visibility information for a given viewpoint. Hardware *z*-buffers facilitate such calculations in the graphics pipeline. Lighting cues, such as shading, are attained by approximating the ambient, diffuse and specular reflectance of

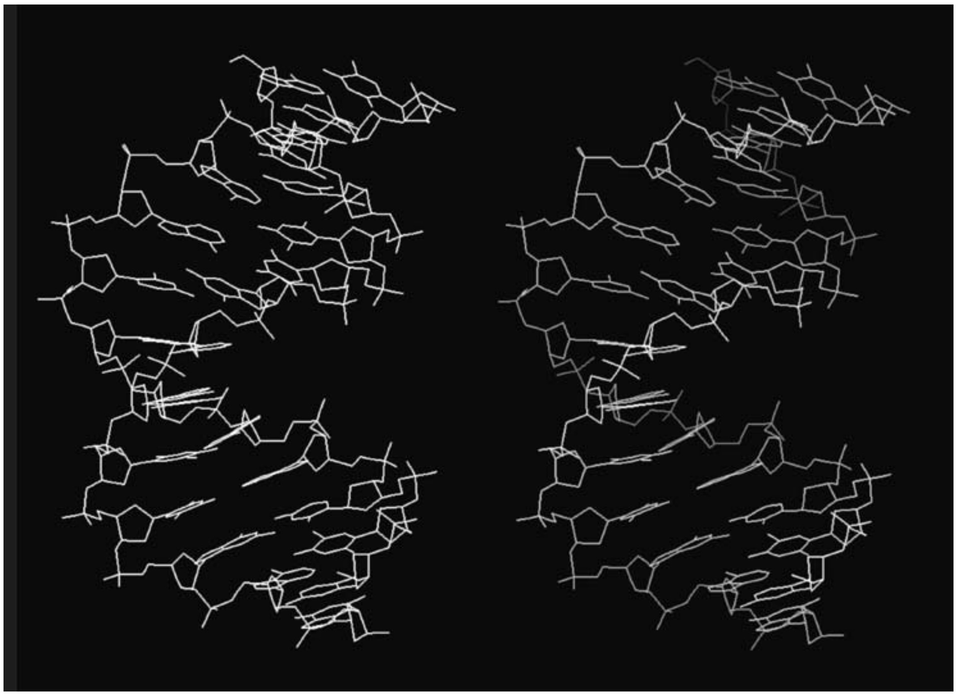

Figure 17.2.3.3
Simple bonding diagram of a DNA structure (PDB code: 140D) (Mujeeb *et al.*, 1993). On the left all lines are of equal intensity. On the right the lines are depth-cued to show which parts of the structure are closer to the viewer.

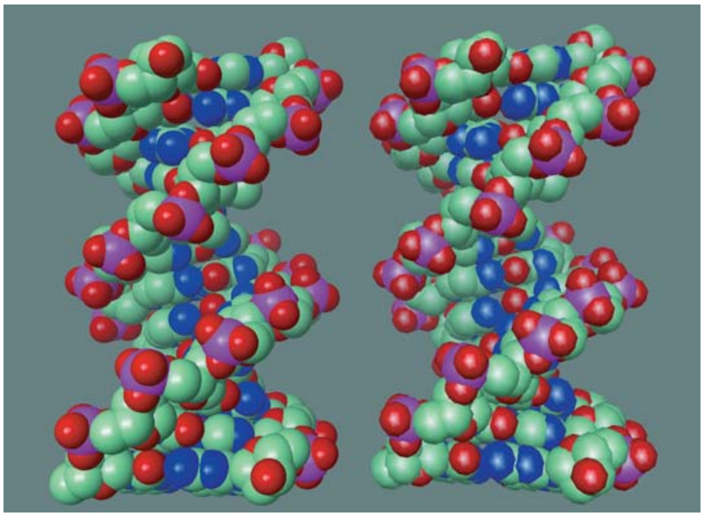

Figure 17.2.3.4
CPK representation of the same DNA structure as in Fig. 17.2.3.3. The model on the left uses highly tessellated spheres for the atoms, while the one on the right uses a coarser tessellation. The Gouraud shading model produces some lighting artifacts, such as the star-shaped highlights, which are most apparent on the right-hand figure. This is due to colour interpolation between the facet vertices.

the geometry using Lambert's law. Because typical surfaces are composed of polyhedral facets, interpolation schemes are used to produce smooth shaded representations. The most common technique used for molecular graphics is known as Gouraud shading (Gouraud, 1971), which interpolates the shaded colour values assigned at the vertices across the polyhedral face (Fig. 17.2.3.4). Phong shading (Phong, 1975), a more accurate but costly technique, interpolates the values of the normals of the facets to produce a more realistic rendering. Shading templates for specific geometries, such as spheres, can give very smooth results without having to resort to large polyhedral descriptions for each sphere. In the past, this approach was implemented in the graphics hardware design, resulting in very fast sphere rendering for molecular applications. With the advent of consumer-level 3-D graphics these specialized features have become increasingly rare. Shadows may also provide useful three-dimensional cues in viewing molecular objects, but may also be confusing when they provide too much visual contrast or clutter. Ray tracing is a general technique for producing a complete reflectance and shadow rendering of a three-dimensional scene. It can, however, be very costly in computational time, since every light ray in the final image must be iteratively traced back to its source. Faster approximations for shadow rendering have been implemented that work well for molecular scenes (Gwilliam & Max 1989; Lauher, 1990).

A number of useful surface representations have been developed that describe the interaction of a molecule with the surrounding solvent. Perhaps the most widely used are the solvent-accessible surface (Lee & Richards, 1971) and the molecular surface (Richards, 1977; Connolly, 1983; Sanner *et al.*, 1996), sometimes referred to as the Connolly or solvent-excluded surface (Fig. 17.2.3.5). For large molecules, such as proteins, which have many atoms buried from solvent, these surfaces have proven to be important in studying molecular interactions. They not only help to visualize the complementarity of interacting molecules, but they are also important in quantifying the entropic changes associated with solvent effects upon binding.

Surface representations have opened up the possibilities of displaying a large variety of computed or experimental molecular properties by mappings onto the surface using colour coding. Electrostatic potential, hydrophobicity, sequence conservation, surface shape and any other characteristic of the molecule that can be projected onto the surface can be colour coded and displayed. Typically, this is accomplished by colouring the vertices of the surface mesh using a colour mapping or scale and interpolating the colour across the polygonal faces of the mesh. Since colour values are interpolated between vertices, this can produce unwanted colour artifacts if there are abrupt spatial changes in the properties displayed, or if the colour interpolation does not correspond to the property mapping (Fig. 17.2.3.6).

Another method for projecting information on a surface is texture mapping, an approach that is analogous to applying an image 'decal' onto the surface. In this approach, instead of assigning colours to the surface vertices, indices are assigned which serve as coordinates into the image to be mapped. Thus, a great amount of detail may be displayed on a surface mesh that has relatively few polygons describing the geometry. Texture mapping has been used extensively in highly interactive graphics, such as flight simulators and video games, since transformation of the geometry tends to be the computational bottleneck. Since texture mapping requires an indexing scheme that relates an image to a set of geometric vertices on the molecular surface, one needs a

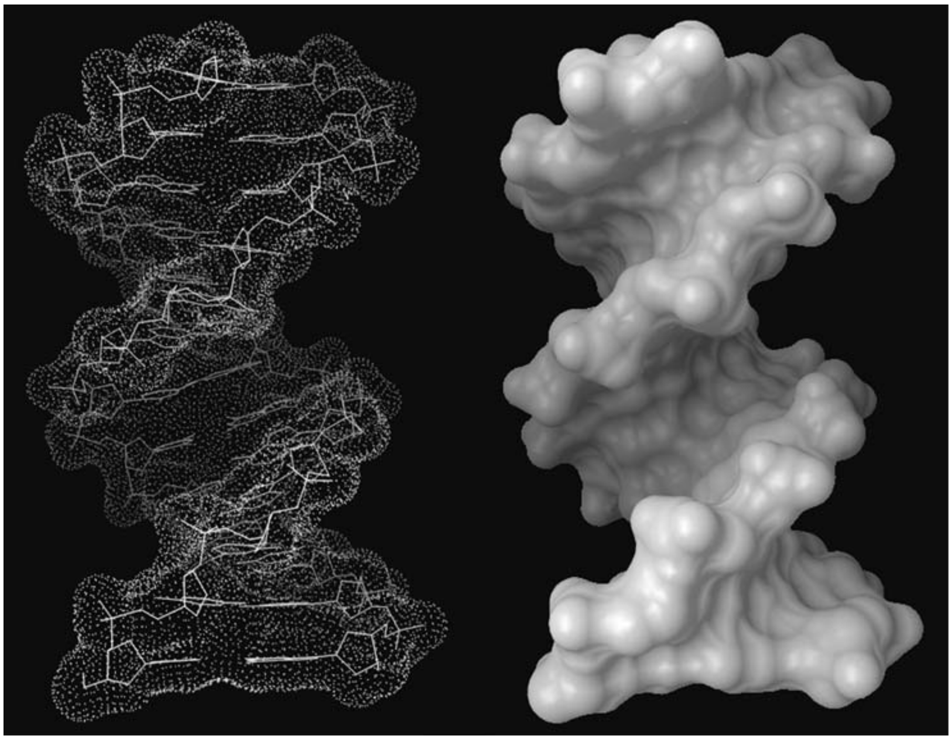

Figure 17.2.3.5
Solvent-excluded surface of the DNA structure using a water probe radius of 1.5 Å. The figure on the left shows a depth-cued dot surface, while the figure on the right shows a Gouraud-shaded triangulated surface.

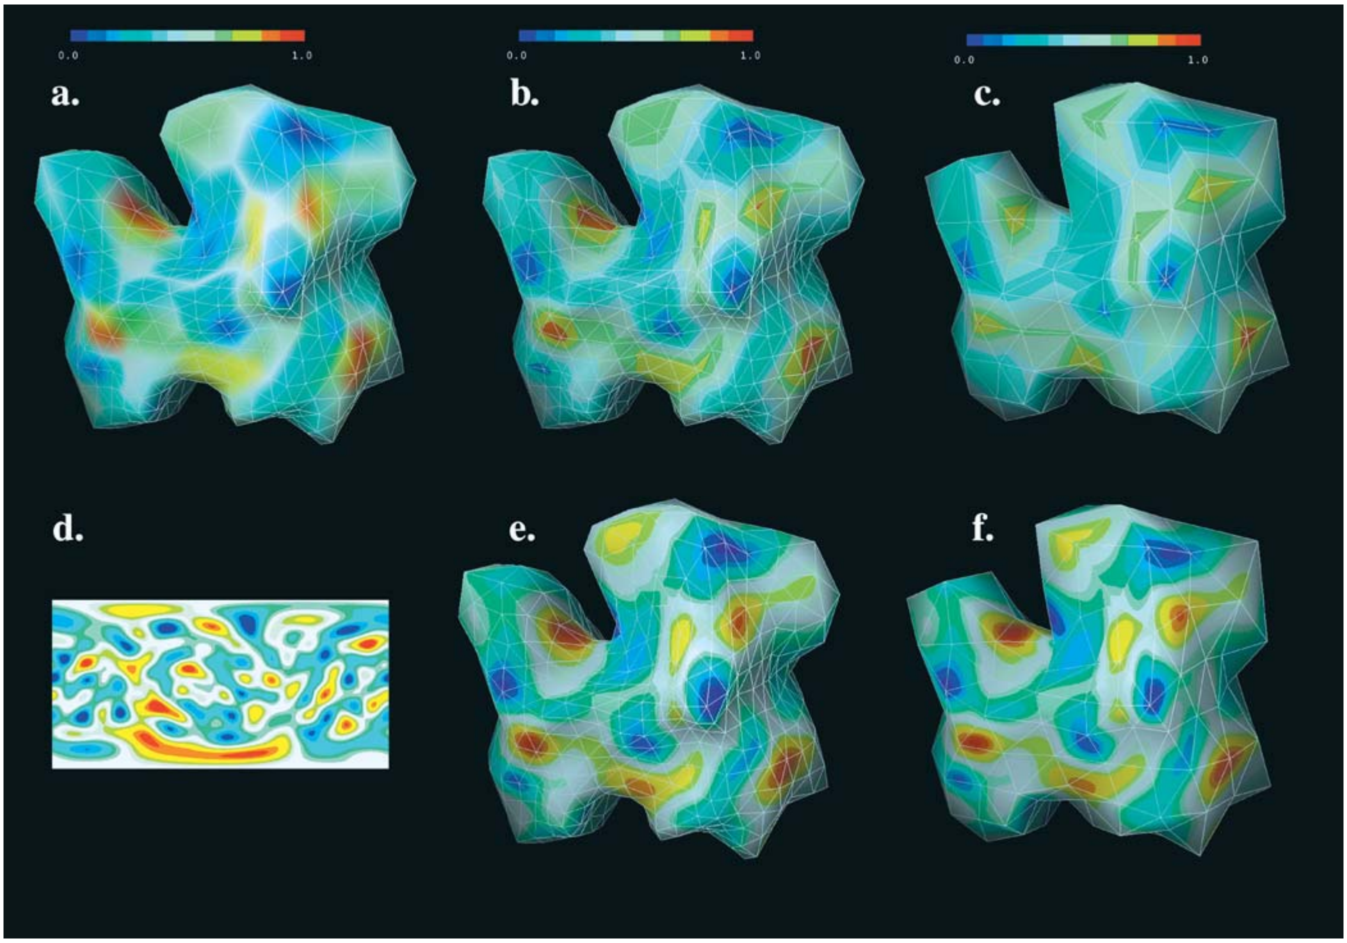

Figure 17.2.3.6

Hydrophobicity mapped onto a molecular surface. A spherical-harmonic approximation of the actin monomer solvent-excluded surface is shown. (*a*) Vertex colouring of a medium-mesh tessellated surface. The hydrophobicity colour scale is shown above. Notice that the colours blend between vertices, producing colour artifacts in relationship to the property scale. (*b*) The same medium-mesh representation as in (*a*) but using a property-based (one-dimensional) texture map, applying the same colour scale. Notice that the boundaries between the colours are distinct, even when they intersect vertices. Here the property value is interpolated. (*c*) A coarser mesh showing the same texture-mapping technique used in (*b*). Since the properties are only sampled at the vertices of the mesh, the finer details of the mapping are lost at this coarse triangulation. (*d*) A two-dimensional texture map created as a 'Mercator-like' projection in spherical coordinates (θ, φ) from the same hydrophobicity scale used in (*a*)–(*c*). (*e*) The 2-D texture map shown in (*d*) mapped onto the medium-mesh actin surface. Notice that the linear nature of the interpolation seen in (*b*) using the same mesh is no longer present. (*f*) The same 2-D texture map applied to the coarse-mesh surface of actin. Notice that, unlike in (*c*), the detail of the texture map is preserved independent of the mesh.

rational way of producing such a map. For one-dimensional texture maps, this is relatively easily accomplished by assigning the texture index of each vertex to an appropriate property scale (Teschner *et al.*, 1994) (Fig. 17.2.3.6). This approach, however, is still tied to the level of triangulation. The more general two-dimensional or location-based surface texture mapping requires a global scheme for assigning texture indices. While the original molecular surface geometry does not lend itself directly to this type of texture mapping, recent analytical approximations to these surfaces, such as spherical-harmonics-based molecular surfaces (Duncan & Olson, 1993), provide simple hierarchical meshing schemes that can be easily texture mapped by using a 'Mercator'-like projection between the image and the molecular surface (Duncan & Olson, 1995) (Fig. 17.2.3.6).

17.2.3.2. Volumetric representation

Molecular properties are not confined to bonds and surfaces. These, in fact, are geometric constructs or abstractions of the time-dependent volumetric characteristics of molecules. In crystallography, electron density is the primary volumetric property to be visualized. Other derived or computed volumetric properties have become important to visualize as well, especially for macromolecules and their complexes. Electrostatic potential and field gradients help establish a molecule's effect at a distance, and a variety of volumetric atomic affinity potentials or grids (Goodford, 1985) can provide a picture of the types of molecular interactions that are energetically favoured.

Traditionally, electron density and other volumetric properties have been displayed as isocontour or isosurface representations, in which lines or surfaces of constant value are rendered in planes or in 3-D space to reveal characteristics of the volumetric property. Early computer-graphic pen plots of planar Fourier projections of electron density were usually sufficient to reveal atomic structure. As the molecules of study became larger and more complex, stacks of two-dimensional slices, creating three-dimensional isocontours, became necessary. The first computer representations of such 3-D isovalue surfaces were composed of three orthogonal 2-D plots – giving the impression of a 'basket weave'. These plots depicted surface isocontours of the three-dimensional density, but had several problems from a computational and representational point of view. Since there were preferred directions of the contours (along the x, y and z axes), particular views were difficult to interpret. Additionally, the three

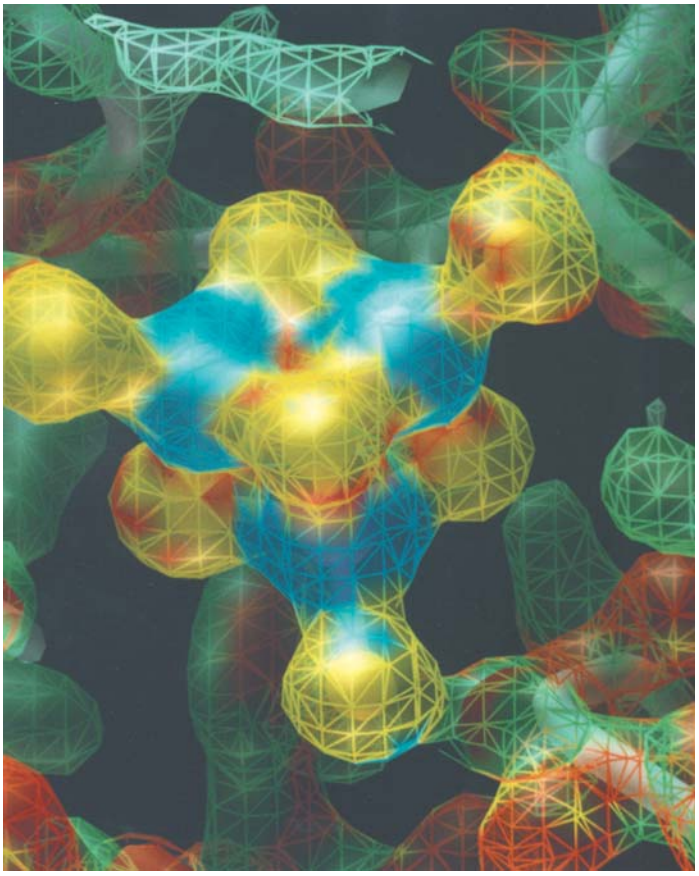

Figure 17.2.3.7
Crystallographic electron-density isosurfaces, showing details of a protein iron–sulfur cluster. The surfaces are coloured by the gradient of the electron density, highlighting the iron and sulfur densities. Image by Michael Pique, The Scripps Research Institute.

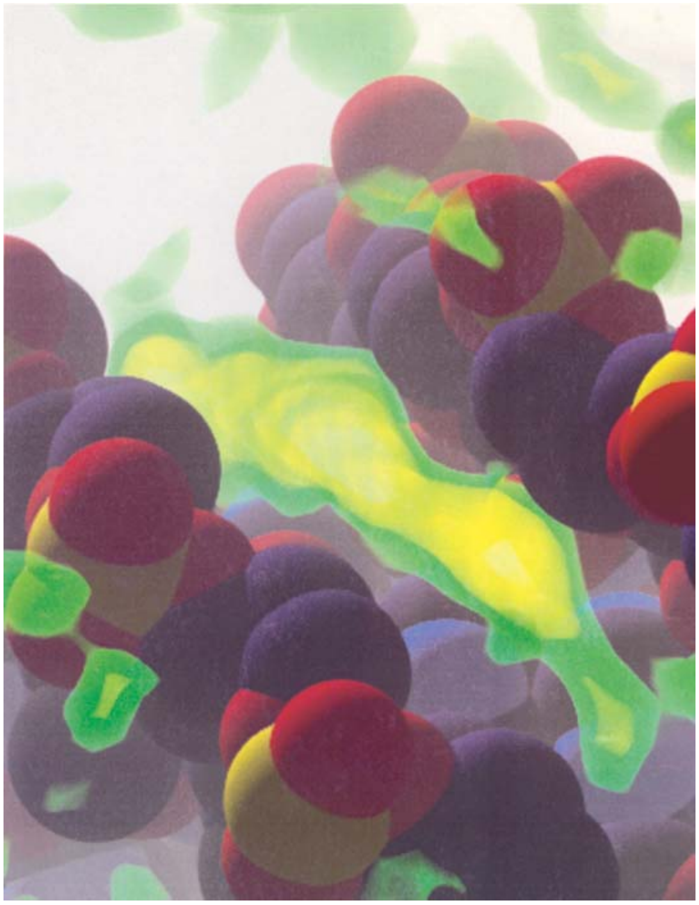

Figure 17.2.3.8

orthogonal contours did not define a well formed triangulated geometric surface, so modern surface rendering techniques could not be applied directly. Moreover, the computation and recomputation of isosurfaces was relatively inefficient. An algorithm to compute directly the three-dimensional isosurface, called 'marching cubes', was devised by Lorenson & Kline (1987) (Fig. 17.2.3.7). This algorithm speeded up the contouring process and enabled shaded surface representation of these surfaces. More recently, the re-computation of isosurfaces has been speeded up through the pre-computation of seed points that span all values of the volume. Using these seed points to flood-fill an isosurface of a given value reduces the contouring computation from a three-dimensional to a two-dimensional calculation. This enables the interactive modification of contour levels for even very large volumes (Bajaj *et al.*, 1996).

While isocontours and isosurfaces have been the dominant modes of volumetric representation in molecular graphics, there has been a trend in scientific visualization to use alternative techniques, termed 'direct volume rendering'. These methods bypass the construction of contours or surfaces to represent values within the volume, and instead use the scalar (or sometimes vector) values within the volume to produce an image directly. A general technique to accomplish this type of volumetric rendering is termed ray casting. If one considers a function that maps the scalar values of a volume into optical properties such as colour and opacity, one can simulate the passage of light rays through the volume, projecting the resulting rays onto the image plane. Given an appropriate transfer function or look-up table, the image represents the distribution of all of the values within the volume, circumventing the need to select only certain values as required for isocontouring. Such techniques have been used extensively in medical tomography (Höhne *et al.*, 1989) and electron microscopy (Kremer *et al.*, 1996; Hessler *et al.*, 1996). Their use has also been explored in the rendering of volumetric properties of molecules (Goodsell *et al.*, 1989). The images that are obtained by direct volume rendering tend to appear cloud-like, with soft edges. While this may be a 'true' representation of the molecular characteristics, it is sometimes difficult to interpret visually. Techniques for imparting shading cues into these renderings by using gradient information in the volume has made this type of rendering more interpretable (Drebein *et al.*, 1988). Another potential drawback to these methods is the cost of the computations. Since these methods require computing the effect of every element of the volume, the amount of computation scales as the cube of the linear dimension. There have been several clever software and hardware approaches to overcoming this problem. One novel hardware approach is to use three-dimensional texture mapping. By stacking texture-mapped planes to represent the colour and opacity of the volume, and using the hardware depth-buffer capabilities to compose the final image in the viewing plane, one can manipulate and render reasonable-size volumes (128^3) at highly interactive rates. For molecular visualization, one would like to be able to represent both geometric and volumetric characteristics in the same rendering to visualize, for instance, model and data (Fig. 17.2.3.8). The three-dimensional texture-mapping approach enables this easily, since the planes upon which the volume data are mapped are in fact geometric. Other direct-volume rendering codes provide this capability as well.

17.2.3.3. *Information visualization*

While molecular-structure research deals directly with objects in three dimensions, it is at times advantageous to abstract this three-dimensional information into diagrams that show relationships that are not readily apparent by examination of a set of geometric models or volumes themselves. This type of representation is broadly termed 'information visualization'. In the arena of molecular structure, probably the best known and most widely used diagram of this type is the Ramachandran plot (Ramachandran & Sasisekharan, 1968), which maps the positions of each of a protein's amino-acid residues into the backbone torsion-angle space of φ and ψ. Such a diagram readily pinpoints the parts of the protein backbone that have unusual (and sometimes erroneous) configurations. It also nicely shows the clustering of residues into the standard secondary structural motifs and their variations. There have been several enhancements of the Ramachandran plot over the years, some of which superimpose computed energy contours or colour-code residues by characteristics such as sequence order.

Another visualization approach that has become very useful is the distance matrix plot, and its derivative, the difference distance matrix (Phillips, 1970). By constructing a matrix of distances between each amino-acid α-carbon and contouring or colouring the resulting values, one can readily see the patterns of α-helices and β-sheets within the structure. An advantage of this type of visualization is that it is coordinate-frame independent. Thus two structures can be compared for features without first superposing their coordinates in the same frame. This approach also works well when comparing two different structures of the same molecule, where there may be some movement between the two. By computing the distance matrix for each structure, and then computing the difference between the two distance matrices, the resulting difference distance matrix will indicate those parts of the structure that stay in the same relative relationships and those that may move relative to each other (Fig. 17.2.3.9).

Animating trajectories of molecular structures and changes in volumetric properties over time is one way to look for trends and patterns in molecular dynamics and other time-course simulations. However, other modes of information visualization can assist analysis and communication of results, sometimes more effectively. Plotting an array of small images showing the time course of key properties can reveal patterns that may be difficult to see in a trajectory. For instance, using the program *MolMol* (Koradi *et al.*, 1996), the time course of the seven nucleic-acid backbone torsion angles during a dynamics simulation of an RNA polynucleotide can be plotted on a circular graph (starting from the centre and progressing outward) to uncover patterns of change and correlation between a large number of variables over time.

In addition to the enormous amount of information generated by computational simulations of molecular dynamics, dockings and other multi-structure, multi-modal techniques, the floodgates of molecular information have opened, gushing data from genomics and high-throughput structure determination. Thus, the need for novel visualization methods has become even more acute. Circle maps defining genomic structure at various levels of detail and annotation have become a common graphical form for organizing and communicating the positional and functional aspects of genome structure. Aligned nucleic acid or amino-acid sequences coded by conservation, chemical property, or any number of other functional relationships have become the *lingua franca* of gene hunters and gatherers. As the protein structure database continues its exponential growth, the opportunities for defining and refining structural family relationships abound. Developing methods for effectively visualizing the relationships that arise from all-by-all computational comparisons of the entire database is an important current challenge in molecular graphics.

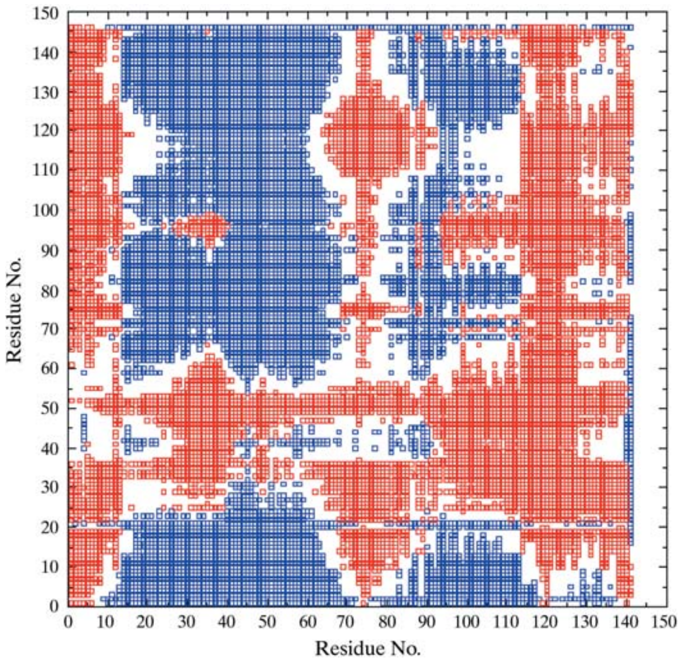

Figure 17.2.3.9
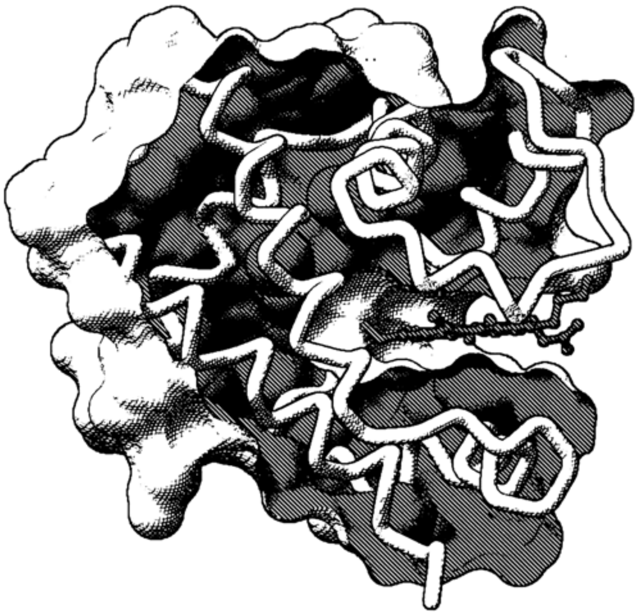
A difference distance matrix plot of the α_1–β_2 interface of haemoglobin in the T to R transformation. The *x* axis represents the α_1 subunit and the *y* axis the β_2 subunit. Red points indicate residues that are closer following the transformation and blue points indicate residues that move farther apart. Plot by Raj Srinivasan, Johns Hopkins University.

17.2.4. Presentation graphics

Much of molecular graphics can be classified as working or 'throw-away' graphics. Typically this involves the interactive creation of graphical representations on screen or paper that are used in the course of research to build, modify and analyse molecular structures, their motions and interactions. Such graphics need only be intelligible to the researchers involved. On the other hand, a presentation or publication graphic must be able to stand on its own to convey information to a broader audience. Thus it requires additional thought and work in its creation. It is unfortunate that many scientists simply capture the working graphics on their computer screens for use in publications or other forms of communication. Both interpretability and intelligibility may suffer badly if a number of issues are not considered in the production of a presentation graphic: What is the medium of publication? What is the main point of the graphic? Who are the target audience? How will reproduction or the viewing environment affect the impact of the graphic? Even seemingly simple issues such as when and how to use colour can in reality be a complex mixture of aesthetics, psychology, technology and economics. While an in-depth discussion of these issues is beyond the scope of this chapter, it is worthwhile to look at two categories of publication graphics, illustration and animation, in this context.



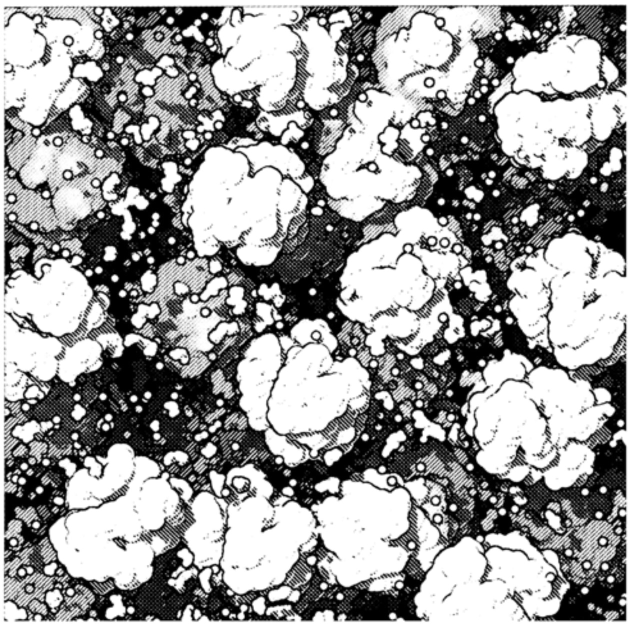


Figure 17.2.4.1
Line-art molecular illustration. The figure on the left depicts the α-carbon backbone and molecular surface of the α subunit of haemoglobin (PDB code: 2hhb). Outlines define the shapes of the surfaces and tubes, and contour lines enhance their three-dimensionality. Hatch lines, normally used for shadows, are used here to darken the inside of the molecular surface. The figure on the right shows the interior of a human red blood cell (300 Å^3), showing all molecules except water. The picture is drawn with outlines defining each molecule. Shadows and depth cuing are used to enhance the three-dimensional character of the image. Contour lines are not used. From Goodsell & Olson (1992).

17.2.4.1. Illustration

In print media, shaded colour images can present a number of difficulties. In addition to the issue of cost, colour shifting, reproducibility and loss of detail in the half-toning process may lead to less than the desired result. Simple line art is an effective way to bypass many of these complications. Since the advent of printing in the middle ages, artists and scientists have explored the problems of creating illustrations within the limitations of the printing process. Over time, artists have built a vocabulary of outlines, hatched shading and varied textures to simplify and clearly portray an object. While the creation of such illustrations was time consuming and required considerable artistic talent, they effectively portrayed the observational science of the day. The advent of computers and computer graphics removed any requirement for skilled hand draftsmanship in the production of molecular representations, but did not solve all of the problems of good illustration. As mentioned above, prior to the widespread use of interactive computer graphics, molecular structures were often published as outline drawings of ball-and-stick models using programs such as *ORTEP* or *PLUTO* (Motherwell & Clegg, 1978). More recently, programs such as *MOLSCRIPT* (Kraulis, 1991) have re-established the popularity of line-art illustration in the molecular realm. A good *ORTEP* drawing usually took a great deal of preparation time in order to get the best representation and viewpoint to display the structure effectively. As the visual repertoire of molecular structure has expanded to a wide variety of shapes including ribbons, tubes and solvent-based surfaces, the challenge of automating the general illustration process has grown. A number of techniques have been developed in the computer-graphics community to generate images in the style of technical or artistic illustrations (Fig. 17.2.4.1). These approaches use lighting, depth information and geometry to produce black-and-white drawings with shapes defined by silhouette lines and cross-hatched shading, and details shown by a variety of textures. *MOLSCRIPT* has used some of these techniques for ribbon and ball-and-stick renderings. More general applications of these approaches to molecular illustration have also been described by Goodsell & Olson (1992).

A significant advantage of digital black-and-white illustration is the efficiency of representation. Since each picture element takes only a single bit of information (black or white), and since there are typically large areas that are of constant value, these

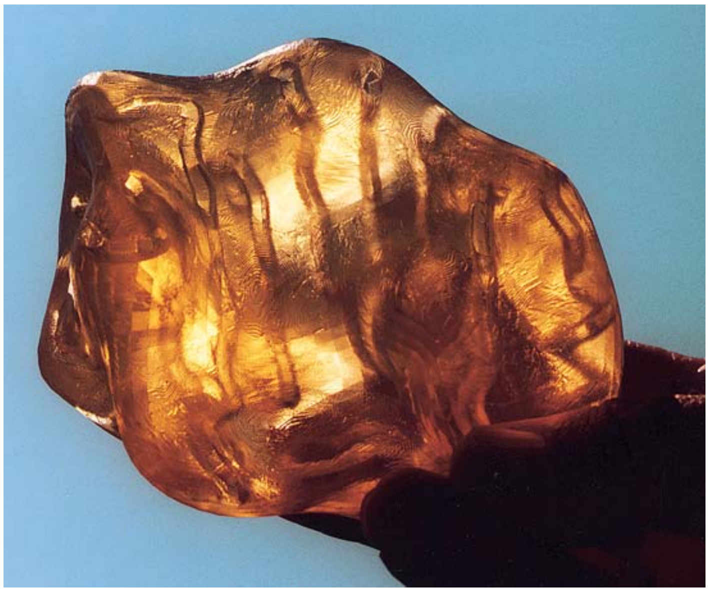

Figure 17.2.4.2
A stereolithographic model of betalactamase inhibitory protein (BLIP). The model depicts the shape of the molecule as represented by a spherical-harmonic approximation of the solvent-excluded surface. Inside the surface is a hollow tube which follows the α-carbon trace of the protein backbone. The model was designed by Michael Pique and Arthur Olson, and fabricated on a 3D systems SLA 1000 by Beryl Hodgson.

images can be compressed, stored, transmitted and printed very efficiently. Thus, with the advent of electronic web publication, such illustrations represent an attractive alternative to full colour. These same characteristics represent significant advantages for the digital transmission and use of animated sequences as well.

17.2.4.2. Animation

Computer-graphic molecular animations began to appear in the late 1960s. Recording directly off their vectorscope, Levinthal and colleagues in Project Mac produced a record of an interactive molecular modelling session in 1967. In the early 1970s, a number of molecular animations were produced to convey new scientific results. Wilson at UC San Diego showed vibrational modes of small molecules in a film produced frame-by-frame on a vectorscope. Parr & Polyani painstakingly filmed pen plotter drawings of space-filling diatomic molecules to animate a bimolecular chemical reaction. Sussman & Seeman produced a black-and-white vector animation of the dinucleotide UpA structure in 1972 by recording directly off a vectorscope. Seeman, Rosenberg & Meyserth produced a more ambitious molecular animation in 1973 entitled *Deep Groove*, which depicted the structure of double helical segment ApU CpC and its implications for more extended DNA geometry. This film was shot in colour, using a monochrome vectorscope and multiple exposures through a colour filter wheel. Around this time, Knowlton, Cherry & Gilmer at Bell Labs used early frame-buffer devices to display and animate patterns of crystal growth based upon aggregation of spheres. In the mid-1970s, Porter & Feldman had developed a scan-line based CPK representation for raster displays and had animated molecular structures, and Langridge and co-workers had taken up recording off the black-and-white vector displays then available. By the end of the 1970s, Max had produced high-quality animations of DNA using a high-resolution Dicomed film writer (Max, 1983) and Olson had used an early colour vector display from Evans and Sutherland to produce an eight-minute animation depicting the structure of tomato bushy stunt virus (Olson, 1981). By the early 1980s, animation projects became more ambitious. Olson produced large-screen OmniMax DNA and virus animation segments for Disney's EPCOT center in 1983. Max produced a red–blue stereo OmniMax film for Fujitsu entitled *We Are Born of Stars*, which included a continuous scene depicting the hierarchical packaging of DNA from atoms to chromosomes, based on the best current model of the time.

Computer-graphics animation has presented both great potential and significant challenges to the molecular scientist wishing to communicate the results of structural research. Animation can not only enhance the depiction of three-dimensional structure through motion stereopsis, it can show relationships through time, and demonstrate mechanism and change. The use of pans, zooms, cuts and other film techniques can effectively lead the viewer through a complex scene and focus attention on specific structures or processes. The vocabulary of film, video and animation is familiar to all, but can be a difficult language to master. While short animations showing simple rotations or transitions between molecular states, or dynamics trajectories, are now routinely made for video or web viewing, extended animations showing molecular structure and function in depth are still relatively rare. The time, tools and expertise that are required are not generally available to structural researchers.

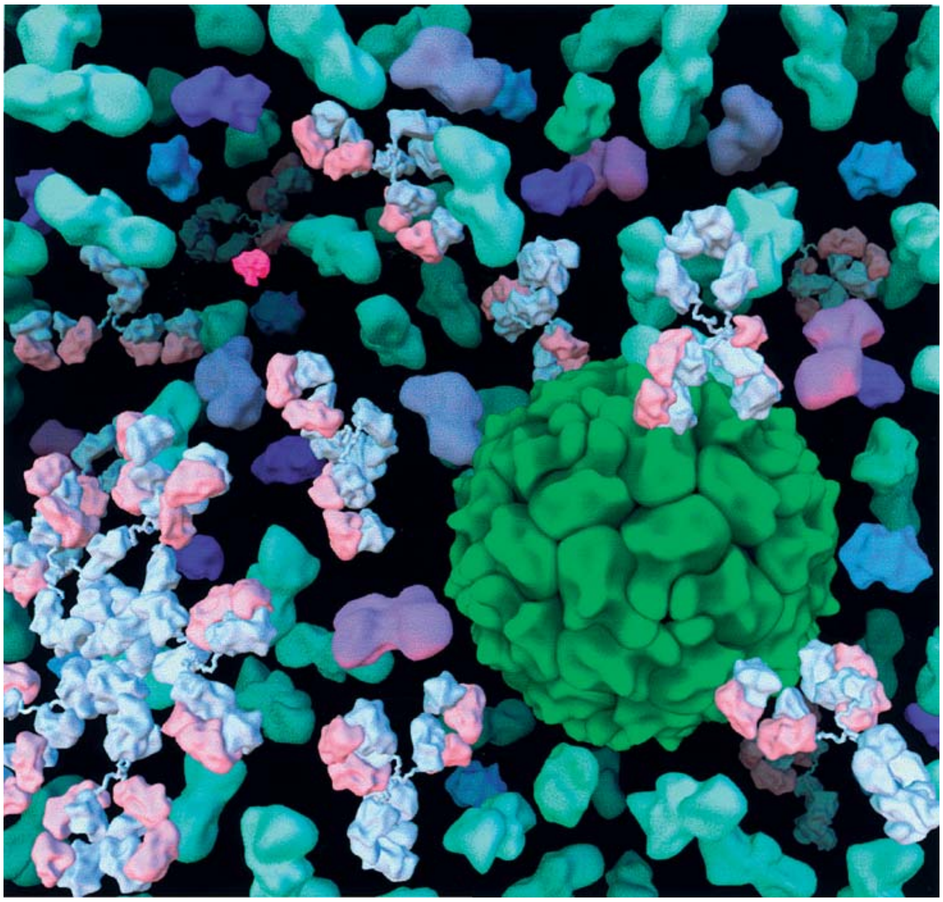

Figure 17.2.5.1

This image represents a volume of blood plasma 750 Å on a side. Within the three-dimensional model, antibodies (Y- and T-shaped molecules in light blue and pink) are binding to a virus (the large green spherical assembly on the right), labelling it for destruction. It shows all macromolecules present in the blood plasma at a magnification of about 10 000 000 times. This model is composed of over 450 individual protein domains, ranging in size from the 60 protomers making up the poliovirus to a single tiny insulin molecule (in magenta). The model was constructed using atomic level descriptions for each molecule, for a total of roughly 1.5 million atoms. Detailed surfaces were computed for each type of protein using *MSMS* by Michel Sanner and then smoothed to a lower resolution using the *HARMONY* spherical-harmonic surfaces developed by Bruce Duncan. The model geometry contains over 1.5 million triangles.

17.2.4.3. The return of physical models

While the use of physical models of molecules has largely been replaced by computer graphics, new computer-driven rapid-prototyping technologies which originated in the manufacturing sector have begun to be utilized in the display of molecular structure. A number of 'three-dimensional printing' methods have been developed to build up a physical model directly from a computational surface representation of an object (Burns, 1954). One of the earliest methods, stereolithography, uses a resin which is polymerized when exposed to laser light of a given wavelength. The laser is passed through a vat of the liquid resin and is lowered, layer-by-layer as it plots out the shape of the object (Fig. 17.2.4.2). Other approaches build up layers of paper or plastic through lamination or deposition. These methods have been used by a number of scientists to produce various representations of molecular structure (Bailey *et al.*, 1998). The ability to hold an accurate representation of a molecular surface in one's hand and feel its shape can give great insight, not only to people with visual impairments, but to anyone. Moreover, when one is dealing with processes such as docking and assembly, these physical models can add a haptic and manipulative appreciation of the nature of the problem. While at this point colour has not been implemented in these technologies, there remains the promise that such automated production of molecular models will enhance the communication and appreciation of molecular structure.

17.2.5. Looking ahead

Moore's law has already delivered on the promise of three-dimensional graphics capability for the desktop and laptop. The internet and World Wide Web have made molecular structure data and display software available to the masses. Have molecular graphics reached a stage of maturity beyond which only small incremental changes will be made?

The Human Genome Initiative and high-throughput structure determination are beginning to change the scope of the questions asked of molecular modelling. Prediction of function, interactions, and large-scale assembly and mechanism will become the dominant domain of molecular graphics and modelling. These tasks will challenge the capabilities of the hardware, software and, particularly, the user interface. New modes of interacting with data and models are coming from the computer-graphics community. Molecular docking and protein manipulation using force-feedback devices have been demonstrated at the University of North Carolina (Brooks *et al.*, 1990). The same team has developed a 'nanomanipulator' which couples a scanning atomic force microscope with stereoscopic display and force-feedback manipulation to control and sense the positioning and interactions of the probe within the molecular landscape (Taylor *et al.*, 1993). The challenge of bridging across the scales of size and complexity of the molecular world may lead us into the realm of virtual reality. Data from X-ray crystallography are being combined with data from large molecular complexes, characterized by electron microscopy. These data, in turn, can be integrated with those from optical confocal microscopy and other imaging techniques. With structures of molecules, assemblies and distributions, as well as data on molecular inventories, we can start to piece together integrated pictures of cellular environments, but with full atomic modelling at the base (Fig. 17.2.5.1). Thus, while climbing around inside a protein molecule might not add much in the way of perceptual advantage, navigating through the molecular environment of a cell may prove to be instructive as well as inspirational.

PART 18. REFINEMENT

Chapter 18.1. Introduction to refinement

L. F. Ten Eyck and K. D. Watenpaugh

18.1.1. Overview

Methods of improving and assessing the accuracy of the positions of atoms in crystals rely on the agreement between the observed and calculated diffraction data. Calculation of diffraction data from an atomic model depends on the theoretical model of scattering of X-rays by crystals discussed in *IT* B (2008) Chapter 1.2. The properties of the measured data are discussed in *IT* C (2004) Chapters 2.2 and 7.1–7.5, and the mathematical basis of refinement of structural parameters is discussed in *IT* C Chapters 8.1–8.5. This chapter concentrates on the special features of macromolecular crystallography.

18.1.2. Background

Macromolecular crystallography is not fundamentally different from small-molecule crystallography, but is complicated by the sheer size of the problems. Typical macromolecules contain thousands of atoms and crystallize in unit cells of around a million cubic ångstroms. The large size of the problems has meant that the techniques applied to small molecules require too many computational resources to be directly applied to macromolecules. This has produced a lag between macromolecular and small-molecule practice beyond the limitations introduced by generally poorer resolution. In essence, macromolecular refinement has followed small-molecule crystallography. Additional complexity arises from the book-keeping required to describe the macromolecular structure, which is usually beyond the capabilities of programs designed for small molecules.

Fitting the atom positions to the calculated electron-density maps (Fourier maps) was a standard method until the introduction of least-squares refinement technique in reciprocal space by Hughes (1941). A less computationally intense method of calculating shifts using difference Fourier maps (ΔF methods) was introduced by Booth (1946*a*,*b*). By the early 1960s, digital computers were becoming generally available and least-squares refinement methods became the method of choice in refining small molecules. The program *ORFLS* developed by Busing *et al.* (1962) was perhaps the most extensively used. In the late 1960s, as protein structures were being determined by multiple isomorphous replacement (MIR) methods (see Part 12 and Chapter 2.4 in *IT* B), methods of improving the structural models derived from the electron-density maps were being studied. Diamond (1971) introduced the use of a constrained chemical model in the fitting of a calculated electron-density model to an MIR-derived electron-density map in a 'real-space refinement' procedure. Diamond commented that phases derived from a previous cycle of real-space fitting could be used to calculate the next electron-density map, but this was not done. Watenpaugh *et al.* (1972) first showed in 1971 that ΔF refinement methods could be applied to both improve the model and extend the phases from initial MIR or SIR (single isomorphous replacement) experimental phases. Watenpaugh *et al.* (1973) also applied least-squares techniques to the refinement of a protein structure for the first time using a 1.54 Å resolution data set. Improvement of the phases, clarification of the electron-density maps and interpretation of unknown sequences in the structure were clearly evident, although chemical restraints were not applied. The adaptation by Hendrickson & Konnert of the restrained least-squares refinement program developed by Konnert (Konnert, 1976; Hendrickson, 1985) became the first extensively used macromolecular refinement program. At this time, refinement of protein models became practical and nearly universal. Model refinement improved models derived from structures determined by isomorphous replacement methods and also provided the means to improve structural models of related protein structures determined by molecular replacement methods (see Part 13 and *IT* B Chapter 2.3).

By the 1980s, it became clear that additional statistical rigour in macromolecular refinement was required. The first and most obvious problem was that macromolecular structures were often solved with fewer observations than there were parameters in the model, which leads to overfitting. Recent advances include cross validation for detection of overfitting of data (Brünger, 1992); maximum-likelihood refinement for improved robustness (Pannu & Read, 1996; Murshudov *et al.*, 1997; Bricogne, 1997; Adams *et al.*, 1999); improved methods for describing the model with fewer parameters (Rice & Brünger, 1994; Murshudov *et al.*, 1999); and incorporation of phase information from multiple sources (Pannu *et al.*, 1998). These improvements in the theory and practice of macromolecular refinement will undoubtedly not be the last word on the subject.

18.1.3. Objectives

A variety of methods are employed to improve the agreement between observed and calculated macromolecular diffraction patterns. Some of the more popular methods are discussed in the different sections of this chapter. In part, the different methods arise from focusing on different goals during different stages of model refinement. Bias generated by incomplete models, and radius of convergence, are important considerations at early stages of refinement, because the models are usually incomplete, contain significant errors in atom parameters and may carry errors from misinterpretation of poorly phased electron-density maps. During this stage of the process, the primary concern is to determine how the model of the chain tracing and conformation of the residues should be described. In later stages, after the description of the model has been determined, the objective is to determine accurate estimates of the values of the parameters which best explain the observed data. These two stages of the problem have different properties and should be treated differently.

Copyright © 2012 International Union of Crystallography

18.1.4. Least squares and maximum likelihood

'Improving the agreement' between the observed and calculated data can only be done if one first decides the criteria to be used to measure the agreement. The most commonly used measure is the L_2 norm of the residuals, which is simply the sum of the squares of the differences between the observed and calculated data (*IT* C Chapter 8.1),

$$L_2(\mathbf{x}) = \|w_i[y_i - f_i(\mathbf{x})]\| = \sum_i w_i[y_i - f_i(\mathbf{x})]^2, \qquad (18.1.4.1)$$

where w_i is the weight of observation y_i and $f_i(\mathbf{x})$ is the calculated value of observation i given the parameters $\mathbf{x}$. In essence, least-squares refinement poses the problem as 'Given these data, what are the parameters of the model that give the minimum variance of the observations?'. The L_2 norm is strongly affected by the largest deviations, which is not a desirable property in the early stages of refinement where the model may be seriously incomplete. In the early stages, it may be better to refine against the L_1 norm,

$$L_1 = \sum_i w_i|[y_i - f_i(\mathbf{x})]|,$$

the sum of the absolute value of the residuals. At present, this technique is not used in macromolecular crystallography.

The observable quantity in crystallography is the diffracted intensity of radiation. Fourier inversion of the model gives us a complex structure factor. The phase information is normally lost in the formulation of $f_i(\mathbf{x})$. This is a root cause of some of the problems of least-squares refinement from poor starting models. Many of the problems of least-squares refinement can be addressed by changing the measure of agreement from least squares to maximum likelihood, which evaluates to the likelihood of the observations given the model. In this formulation, the problem is posed as 'Given this model, what is the probability that the given set of data would be observed?'. The model is adjusted to maximize the probability of the given observations. This procedure is subtly different from least squares in that it is reasonably straightforward to account for incomplete models and errors in the model in computing the probability of the observations. Maximum-likelihood refinement is particularly useful for incomplete models because it produces residuals that are less biased by the current model than those produced by least squares. Maximum likelihood also provides a rigorous formulation for all forms of error in both the model and the observations, and allows incorporation of additional forms of prior knowledge (like additional phase information) into the probability distributions.

The likelihood of a model given a set of observations is the product of the probabilities of all of the observations given the model. If $P_a(\mathbf{F}_i;\ \mathbf{F}_{i,c})$ is the conditional probability distribution of the structure factor $\mathbf{F}_i$ given the model structure factor $\mathbf{F}_{i,c}$, then the likelihood of the model is

$$L = \prod_i P_a(\mathbf{F}_i;\ \mathbf{F}_{i,c}).$$

This is usually transformed into a more tractable form by taking the logarithm,

$$\log L = \sum_i \log P_a(\mathbf{F}_i;\ \mathbf{F}_{i,c}).$$

Since the logarithm increases monotonically with its argument, the two versions of the equation have maxima at the same values of the parameters of the model. This formulation is described in more detail in Chapter 18.2, in *IT* C Section 8.2.1 and by Bricogne (1997), Pannu & Read (1996), and Murshudov *et al.* (1997).

18.1.5. Optimization

Once the choice of criteria for agreement has been made, the next step is to adjust the parameters of the model to minimize the disagreement (or maximize the agreement) between the model and the data. The literature on optimization in numerical analysis and operations research, discussed in *IT* C Chapters 8.1–8.5, is very rich. The methods can be characterized by their use of gradient information (no gradients, first derivatives, or second derivatives), by their search strategy (none, downhill, random, annealed, or a combination of these), and by various performance measures on different classes of problems. These will be discussed more fully in Section 18.1.8.

18.1.6. Data

Resolution, accuracy, completeness and weighting of data all have an impact on the refinement process. Small-molecule crystals usually, but not always, diffract to well beyond atomic resolution. Macromolecular crystals do not generally diffract to atomic resolution. Macromolecular structures are by definition large, which in turn means that the unit cells are large and the number of diffracting unit cells per crystal is small when compared to small-molecule crystals of similar size. Fortunately, the situation can be partially offset with the use of the much more intense radiation generated by synchrotrons (Part 8) and by improved data-collection methods (Parts 7–11). Synchrotron-radiation sources designed to produce intense beams of X-rays for the study of materials are becoming much more readily available. As a consequence, both higher resolution and statistically better data can be obtained. Improvements in area-detector technology, protein purification, cryocrystallography and data-integration software beneficially influence the refinement process.

Refinement of crystal structures is a statistical process. There is no substitute for adequate amounts of accurate, correctly weighted data. Lower accuracy can be accommodated by increased amounts of data and correct weighting. Unfortunately, determining the correct weighting for macromolecular diffraction data is difficult. Maximum-likelihood methods are more robust than least-squares methods against improperly weighted data.

It has been clearly demonstrated that the best procedure for refining small molecules is to include all of the observations as integrated intensities, properly weighted, without preliminary symmetry averaging. Inclusion of weak data and refinement on diffracted intensity does not change the results very much, but has a strong effect on the precision of the parameter estimates derived from the refinement.

The long-standing debate as to whether refinement should be against structure-factor amplitudes or diffracted intensity has been resolved for small-molecule crystallography. Refinement against intensity is preferred because it is closer to the experimentally observed quantity, and the statistical weighting of the data is superior to that obtained for structure-factor amplitudes. If the model is correct and the data are reasonably good, the primary distinction between the two approaches is in the standard uncertainties of the derived parameters, which are usually somewhat better if the refinement is against diffracted intensity.

18.1.7. Models

Atomic resolution models are generally straightforward. A reasonably well phased diffraction pattern at atomic resolution shows the location of each atom. The primary problem (which can be substantial) is deciding how to model any disorder that may be present. Structural chemistry is derived from the model. Macromolecular models generally have most of the structural chemistry built in as part of the model. This approach is required as a direct consequence of having too little data at too limited a resolution to determine the positions of all of the atoms without using this additional information.

There are two procedures for building structural chemistry into a model. The first is to use known molecular geometry to reduce the number of variables. For example, if the distance between two atoms is held constant, the locus of possible positions for the second atom is the surface of a sphere centred on the first atom. This means that the position of the second atom can be specified given the position of the first atom and two variables to locate the point on the sphere – a total of five variables instead of six. Every non-redundant constraint reduces the number of degrees of freedom in the model by one. If the second atom in this example were replaced by a group of atoms with known geometry (*e.g.* a phenyl group containing six atoms), the number of positional parameters could be reduced from 21 to eight. Constrained refinement is discussed extensively in *IT* C Chapter 8.3.

The second procedure is to treat the additional information as additional observations. A bond length is assumed to be an observation, based on other crystal structures, which has a mean value and a variance. This observation is added to the data instead of being used to reduce the number of parameters in the model.

The two approaches have different consequences on the ratio of observations to parameters. If we have N_o observations, N_p parameters and N_r non-redundant geometric features to add to the problem, we have either $C = N_o/(N_p - N_r)$ and $(\mathrm{d}C/\mathrm{d}N_r) = C/(N_p - N_r)$ or $C = (N_o + N_r)/N_p$ and $(\mathrm{d}C/\mathrm{d}N_r) = 1/N_p$, where C is the ratio of observations to parameters. The former are parameter *constraints* and the latter are parameter *restraints*. Constraints are more effective at increasing the ratio of observations to parameters, but since these features are built into the model, it is difficult to evaluate how appropriate they actually are for the problem at hand. Restraints provide an automatic evaluation of the appropriateness of the assumed geometry to the current data, because the deviations from the assumed values can be tested for statistical significance.

The most common constraints and restraints applied to macromolecular crystal structures are those which preserve or reinforce the molecular geometry of the amino acid or nucleotide residues (Chapter 18.3). Expected values for the geometry of these structural fragments are available from the small-molecule crystallographic literature and databases. A further step, which reduces the parameter count substantially, is to treat parts of the molecule as a set of linked rigid groups. This is particularly appropriate for aromatic fragments such as the side chains of phenylalanine, tyrosine, tryptophan and histidine, but can also be appropriate for small groups like valine and threonine. The extreme form of this approach is torsion-angle dynamics (Rice & Brünger, 1994), in which the only variables are torsion angles about bonds, and the position and orientation of the whole molecule. This description of the model works well with the right kind of optimization procedure.

Positional restraints can be parameterized in a variety of ways. For example, the geometry of three atoms can be treated as the three distances involved or as two distances and the angle between them. Several of the more popular restrained refinement programs treat the parameters for bond distances, bond angles and planarity as distances with a set of standard deviations. Others treat them as bond distances, bond angles and torsion angles weighted by the energy terms derived from experimental conditions. Different methods of parameterization and weighing have different effects on the refinement process, but to date these differences are not well characterized. The primary effects should be on the approach to convergence, as all of these formulations are normally satisfied by correct structures.

Additional criteria can be added to the model besides simple geometry. Preservation of bond lengths is usually done by adding terms

$$\sum_{\substack{\text{bonded}\\\text{atoms}}} \left(1/\sigma_{ij}^2\right)\left(d_{ij} - d_{ij}^o\right)^2$$

to the objective function, where d_{ij} is the distance between atoms i and j, d_{ij}^o is the ideal bond length, and σ_{ij} is the weight applied to the bond. This is formally equivalent to treating bond stretching as a spring. Additional energy parameters can be added, such as electrostatic energy terms. Whatever vision of reality is applied to the objective function becomes part of the model.

The atomic displacement factors (B factors) present a different set of problems from the coordinates. The behaviour of these parameters is strongly affected by coordinate errors, and in fact large atomic displacement parameters are frequently used to determine which parts of a structure are likely to contain errors. The B factors are strongly related to the rate at which the diffraction pattern diminishes with resolution and thus cannot be accurately determined unless the diffraction pattern has been measured over a sufficiently wide range of resolution to determine this rate. As a practical matter, it is not feasible to refine individual atomic displacement parameters at resolution less than about 2 Å, and they frequently present problems even in atomic resolution small-molecule structures. In high-resolution small-molecule structures, B factors are frequently represented as anisotropic ellipsoids described by six parameters per atom. In spite of the larger displacements found in macromolecules relative to small molecules, it is rarely possible to support the number of parameters required to refine a structure with independent anisotropic displacement factors. Nevertheless, the B factors of the atoms are essential parts of the crystallographic model. Several methods for reducing the number of independent B factors have been developed. The simplest is group B factors, in which one parameter is refined for all atoms in a particular group of atoms. Another method is to apply a simple model to the change in displacement parameter within a group of atoms. In this treatment, a B factor is refined for one atom, say the C_α atom of an amino-acid residue, and the remainder of the atoms in the residue are assigned displacement parameters that depend on their distance from the C_α atom (Konnert & Hendrickson, 1980). A third method is to enforce similarity of displacement parameters based on the correlation coefficients between pairs of displacement parameters in highly refined high-resolution structures (Tronrud, 1996).

Small-molecule refinement programs also apply restraints to the displacement parameters. The SIMU command of *SHELX* restrains the axes of the anisotropic displacement parameters of bonded atoms to be similar. This approach has been applied to a number of very high resolution macromolecular refinements.

Large B factors do not represent large thermal motions of the atom but rather a distribution of positions occupied by the atom over time or in different unit cells of the crystal. The line between describing atoms with large B factors as distributed about a single point or several points (disordered atoms) is sometimes blurred. At some point, the disorder can become resolved into alternative positions or the atoms disappear from the observable electron density. There are two kinds of disorder that can be easily modelled if data are available to sufficient resolution:

(1) *Static disorder* describes the situation in which portions of the structure have a small number of possible alternative conformations. The atoms in any given unit cell are in only one of the possible conformations, but different cells may have different conformations. Since the diffraction experiment averages the structure over all unit cells in the X-ray beam, the observations correspond to an average structure in which each conformation is weighted according to the fraction of the unit cells containing that conformation. The normal bond-length and angle restraints apply to each conformation, and the fractional occupancy of all conformations should sum to 1.0.

(2) *Dynamic disorder* describes the situation in which portions of the structure are not in fixed positions. This form of disorder is frequently encountered in amino-acid side chains on the molecular surface. The electrons are spread over a sufficiently large volume that the average electron density is very low and the atoms are essentially invisible to X-rays. In such cases, the best model is to simply omit the atoms from the diffraction calculation. They are commonly placed in the model in plausible positions according to molecular geometry, but this can be misleading to people using the coordinate set. If the atoms are included in the model, the atomic displacement parameters generally become very large, and this may be an acceptable flag for dynamic disorder. The hazard with this procedure is that including these atoms in the model provides additional parameters to conceal any error signal in the data that might relate to problems elsewhere in the model.

At high resolution, it is sometimes possible to model the correlated motion of atoms in rigid groups by a single tensor that describes translation, libration and screw. This is rarely done for macromolecules at present, but may be an extremely accurate way to model the behaviour of the molecules. The recent development of efficient anisotropic refinement methods for macromolecules by Murshudov *et al.* (1999) will undoubtedly produce a great deal more information about the modelling of dynamic disorder and anisotropy in macromolecular structures.

Macromolecular crystals contain between 30 and 70% solvent, mostly amorphous. The diffraction is not accurately modelled unless this solvent is included (Tronrud, 1997). The bulk solvent is generally modelled as a continuum of electron density with a high atomic displacement parameter. The high displacement parameter blurs the edges, so that the contribution of the bulk solvent to the scattering is primarily at low resolution. Nevertheless, it is important to include this in the model for two reasons. First, unless the bulk solvent is modelled, the low-resolution structure factors cannot be used in the refinement. This has the unfortunate effect of rendering the refinement of *all* of the atomic displacement parameters ill-determined. Second, omission or inaccurate phasing of the low-resolution reflections tends to produce long-wavelength variations in the electron-density maps, rendering them more difficult to interpret. In some regions, the maps can become overconnected, and in others they can become fragmented.

18.1.8. Optimization methods

Optimization methods for small molecules are straightforward, but macromolecules present special problems due to their sheer size. The large number of parameters vastly increases the volume of the parameter space that must be searched for feasible solutions and also increases the storage requirements for the optimization process. The combination of a large number of parameters and a large number of observations means that the computations at each cycle of the optimization process are expensive.

Optimization methods can be roughly classified according to the order of derivative information used in the algorithm. Methods that use no derivatives find an optimum through a search strategy; examples are Monte Carlo methods and some forms of simulated annealing. First-order methods compute gradients, and hence can always move in a direction that should reduce the objective function. Second-order methods compute curvature, which allows them to predict not only which direction will reduce the objective function, but how that direction will change as the optimization proceeds. The zero-order methods are generally very slow in high-dimensional spaces because the volume that must be searched becomes huge. First-order methods can be fast and compact, but cannot determine whether or not the solution is a true minimum. Second-order methods can detect null subspaces and singularities in the solution, but the computational cost grows as the cube of the number of parameters (or worse), and the storage requirements grow as the square of the number of parameters – undesirable properties where the number of parameters is of the order of 10^4.

Historically, the most successful optimization methods for macromolecular structures have been first-order methods. This is beginning to change as multi-gigabyte memories are becoming more common on computers and processor speeds are in the gigahertz range. At this time, there are no widely used refinement programs that run effectively on multiprocessor systems, although there are no theoretical barriers to writing such a program.

18.1.8.1. Solving the refinement equations

Methods for solving the refinement equations are described in *IT* C Chapters 8.1 to 8.5 and in many texts. Prince (1994) provides an excellent starting point. There are two commonly used approaches to finding the set of parameters that minimizes equation (18.1.4.1). The first is to treat each observation separately and rewrite each term of (18.1.4.1) as

$$w_i[y_i - f_i(\mathbf{x})] = w_i \sum_{j=1}^{N} \left(\frac{\partial f_i(\mathbf{x})}{\partial x_j} \right) (x_j^0 - x_j), \qquad (18.1.8.1)$$

where the summation is over the N parameters of the model. This is simply the first-order expansion of $f_i(\mathbf{x})$ and expresses the hypothesis that the calculated values should match the observed values. The system of simultaneous *observational equations* can be solved for the parameter shifts provided that there are at least as many observations as there are parameters to be determined. When the number of observational equations exceeds the number of parameters, the least-squares solution is that which minimizes (18.1.4.1). This is the method generally used for refining small-molecule crystal structures, and increasingly for macromolecular structures at atomic resolution.

18.1.8.2. Normal equations

In matrix form, the observational equations are written as

$$\mathbf{A}\Delta = \mathbf{r},$$

where $\mathbf{A}$ is the M by N matrix of derivatives, Δ is the parameter shifts and $\mathbf{r}$ is the vector of residuals given on the left-hand sides of equation (18.1.8.1). The *normal equations* are formed by multiplying both sides of the equation by $\mathbf{A}^T$. This produces an N by N square system, the solution to which is the desired least-squares solution for the parameter shifts.

$$\mathbf{A}^T\mathbf{A}\Delta = \mathbf{A}^T\mathbf{r} \text{ or } \mathbf{M}\Delta = \mathbf{b},$$

$$m_{ij} = \sum_{k=1}^{M} w_k \left(\frac{\partial f_k(\mathbf{x})}{\partial x_i}\right)\left(\frac{\partial f_k(\mathbf{x})}{\partial x_j}\right),$$

$$b_i = \sum_{k=1}^{M} w_k[y_k - f_k(\mathbf{x})]\left(\frac{\partial f_k(\mathbf{x})}{\partial x_i}\right).$$

Similar equations are obtained by expanding (18.1.4.1) as a second-order Taylor series about the minimum $\mathbf{x}_0$ and differentiating.

$$\Phi(\mathbf{x}-\mathbf{x}_0) \approx \Phi(\mathbf{x}_0) + \left\langle \left(\frac{\partial\Phi}{\partial x_i}\right)_{\mathbf{x}_0} \middle| (\mathbf{x}-\mathbf{x}_0) \right\rangle + \frac{1}{2}\left\langle (\mathbf{x}-\mathbf{x}_0) \middle| \left(\frac{\partial^2\Phi}{\partial x_i \partial x_j}\right)_{\mathbf{x}_0} \middle| (\mathbf{x}-\mathbf{x}_0) \right\rangle,$$

$$\left|\left(\frac{\partial\Phi}{\partial\mathbf{x}}\right)\right\rangle \approx \left|\left(\frac{\partial^2\Phi}{\partial x_i \partial x_j}\right)_{\mathbf{x}_0}\right| \left.(\mathbf{x}-\mathbf{x}_0)\right\rangle.$$

The second-order approximation is equivalent to assuming that the matrix of second derivatives does not change and hence can be computed at $\mathbf{x}$ instead of at $\mathbf{x}_0$.

18.1.8.3. Choice of optimization method

First-order methods are generally the most economical for macromolecular problems. The most general approach is to treat the problem as a non-linear optimization problem from the beginning. This strategy is used by *TNT* (Tronrud *et al.*, 1987; Tronrud, 1997) and by *X-PLOR* (Kuriyan *et al.*, 1989), although by very different methods.

TNT uses a preconditioned conjugate gradient procedure (Tronrud, 1992), where the preconditioning function is the second derivatives of the objective function with respect to each parameter. In other words, at each step the parameters are normalized by the curvature with respect to that parameter, and a normal conjugate gradient step is taken. This has the effect that stiff parameters, which have steep derivatives, are scaled down, while soft parameters (such as B factors), which have small derivatives, are scaled up. This greatly increases both the rate and radius of convergence of the method.

X-PLOR (and its intellectual descendent, *CNS*) (Chapters 18.2 and 18.6) uses a simulated annealing procedure that derives sampling points by molecular dynamics. Simulated annealing is a process by which the objective function is sampled at a new point in parameter space. If the value of the objective function at the new point is less than that at the current point, the new point becomes the current point. If the value of the objective function is greater at the new point than at the current point, the Boltzmann probability $\exp(-\Delta E/kT)$ of the difference in function values ΔE is compared to a random number. If it is less than the random number, the new point is accepted as the current point; otherwise it is rejected. This process continues until a sufficiently deep minimum is found that the sampling process never leaves that region of parameter space. At this point the 'temperature' in the Boltzmann factor is reduced, which lowers the probability that the current point will move out of the region. This produces a finer search of the local region. The cooling process is continued until the solution has been restricted to a sufficiently small region. There are many variations of the strategy that affect the rate of convergence and the completeness of sampling. The primary virtue of simulated annealing is that it does not become trapped in shallow local minima. Simulated annealing can be either a zero-order method or a first-order method, depending on the strategy used to generate new sampling points. *X-PLOR* treats the fit to the diffraction data as an additional energy term, and the gradient of that 'energy' is treated as a force. This makes it a first-order method.

The first widely available macromolecular refinement program, *PROLSQ* (Konnert, 1976), uses an approximation to the second-order problem in which the matrix is greatly simplified. The parameters for each atom are treated as a small block on the diagonal of the matrix, and the off-diagonal blocks for pairs of atoms related by geometric constraints are also filled in. The sparse set of linear equations is then solved by an adaptation of the method of conjugate gradients.

The most comprehensive refinement program available for macromolecules is the same as the most comprehensive program available for small molecules – *SHELXL98* (Sheldrick, 1993; see also Chapter 18.9). The primary adaptations to macromolecular problems have been the addition of conjugate gradients as an optimization method for cases in which the full matrix will not fit in the available memory and facilities to process the polymeric models required for macromolecules.

18.1.8.4. Singularity in refinement

Unless there are more linearly independent observations than there are parameters to fit them, the system of normal equations has no solution. The inverse of the matrix does not exist. Second-order methods fail in these circumstances by doing the matrix equivalent of dividing by zero. However, the objective function is still defined and has a defined gradient at all points. First-order methods will find a point at which the gradient is close to zero, and zero-order methods will still find a minimum value for the objective function. The difficulty is that the points so found are not unique. If one computes the eigenvalues and eigenvectors of the matrix of normal equations, one will find in this case that there are some eigenvalues that are very small or zero. The eigenvectors corresponding to these eigenvalues define sets of directions in which the parameters can be moved without affecting the value of the objective function. This region of the parameter space simply cannot be determined by the available data. The only recourses are to modify the model so that it has fewer parameters, add additional restraints to the problem, or collect more data. The real hazard with this situation is that the commonly used refinement methods do not detect the problem. Careful use of cross validation and keeping careful count of the parameters are the only remedy.

18.1.9. Evaluation of the model

Macromolecular model refinement is a cyclic process. No presently known refinement algorithm can remove all the errors of chain tracing, conformation, or misinterpretation of electron density. Other methods must be interspersed with refinement to help remove model errors. These errors are detected by basic sanity checks and the use of common sense about the model. This topic is discussed comprehensively in Part 21 and in Kleywegt (2000).

18.1.9.1. Examination of outliers in the model

Refinement-program output listings will normally provide some information on atoms that are showing non-standard bond lengths, bond angles or B factors. In addition, there is other software which can help identify non-standard or unusual geometry, such as *PROCHECK* (Laskowski *et al.*, 1993) and *WHAT IF* (Vriend, 1990). These are very useful in identifying questionable regions of structure but should not be completely relied on to identify errors or how the molecular models may be improved. Overall, the constraints in the model must be satisfied exactly, and the restraints should have a statistically reasonable distribution of deviations from the ideal values.

18.1.9.2. Examination of model electron density

Refinement of the model to improve the agreement between the observed and calculated diffraction data and the associated calculated phases should result in improved electron-density and ΔF maps. Unexplained features in the electron-density map or difference map are a clear indication that the model is not yet complete or accurate. Careful examination of the Fourier maps is essential. Interactive graphics programs such as *XtalView* (McRee, 1993) and *O* contain a number of analysis tools to aid in the identification of errors in the models.

There are several different types of Fourier maps that can be useful in the correction of the models. This topic is discussed extensively in Chapter 15.2. Usual maps include F_o maps, ΔF maps and $(nF_o - mF_c)$ maps. The Fourier coefficients used to compute the maps should be weighted by estimates of the degree of bias as described in Chapter 15.2. While ΔF maps are very useful in highlighting areas in the maps that reflect the greatest difference between the F_o's and F_c's in Fourier space, they do not show the electron density of the unit cell. Positive and negative regions of a ΔF map may be the result of positional errors of an atom or group of atoms, B-factor errors, completely misplaced atoms or missing atoms. F_o maps show the electron density but are biased by the current model. A $(2F_o - F_c)$ map is a combination of an F_o map and a ΔF map which results in a map better showing the changes due to errors. Some investigators prefer using further amplified ΔF contributions by using a $(3F_o - 2F_c)$ map or higher-order terms.

The contribution of the disordered solvent continuum has been discussed previously. Macromolecular crystals also contain significant quantities of discrete or partially discrete solvent molecules (*i.e.* water). Care needs to be taken in adding solvent to a model. Errors in models generate peaks in Fourier maps that can be interpreted as solvent peaks. Hence, adding solvent peaks too early in the refinement process may, in fact, lead to model errors. Automatic water-adding programs are becoming more common; examples include *SHELXL98* and *ARP/wARP* (Lamzin & Wilson, 1997). These programs check if the waters are with in reasonable bonding distances of hydrogen-bonding atoms. There is a distribution of solvent molecules ranging from ones with low B factors at unit occupancy to ones with very large B factors. Various criteria are used to decide on a cutoff in the discrete solvent contribution. A rule of thumb for ambient-temperature data sets is frequently about one solvent molecule per residue in a protein molecule. As more data are being collected at cryogenic temperatures, this ratio is tending to go up. Noise is being fitted if too many peaks in a ΔF map are being assigned as solvent molecules. This can also contribute to reducing R factors on incorrect models. Solvent sites may not be fully occupied. Because of the large B factors and limited range of the diffraction data, the B factors and occupancy are highly correlated. Refinement of occupancy does not usually contribute either to improving a model or to reduction of R factors in structures with up to 2.0 Å resolution data. Beyond 1.5 Å data, it may be possible to refine solvent water occupancies and B factors. At even higher resolution, some programs, such as *SHELXL98*, provide anisotropic refinement methods which may further improve the solvent model while reducing R factors including $R_{\rm free}$.

18.1.9.3. R and R_{free}

Cross validation is a powerful tool for avoiding over-interpretation of the data by a too elaborate model. The introduction of cross validation to crystallography (Brünger, 1992) has been responsible for significant improvement in the quality of structure determinations. A subset of the reflections, chosen randomly, is segregated and not used in the refinement. If the model is correct and the only errors are statistical, these reflections should have an R factor close to that of the reflections used in the refinement. Changes to the model should affect both R and $R_{\rm free}$ similarly. Kleywegt & Jones (1997) have pointed out that it is necessary to treat the selection of free reflections very carefully in the presence of noncrystallographic symmetry.

18.1.10. Conclusion

It is always important to bear in mind that macromolecular crystal structures are models intended to explain a particular set of observations. Statistical measures can determine how well the model explains the observations, but cannot say whether the model is true or not. The distinction between precision and accuracy must always be kept in mind. The objective should not be simply to obtain the best fit of a model to the data, but, in addition, to find all of the ways in which a model does *not* fit the data and correct them. Until the day when all crystals diffract to atomic resolution, the primary objective of refinement of the models will be to determine just how well the structures are or are not determined.

Chapter 18.2. Enhanced macromolecular refinement by simulated annealing

A. T. Brunger, P. D. Adams and L. M. Rice

18.2.1. Introduction

The analysis of X-ray diffraction data generally requires sophisticated computational procedures that culminate in refinement and structure validation. The refinement procedure can be formulated as the chemically constrained or restrained nonlinear optimization of a target function, which usually measures the agreement between observed diffraction data and data computed from an atomic model. The ultimate goal of refinement is to optimize simultaneously the agreement of an atomic model with observed diffraction data and with *a priori* chemical information.

The target function used for this optimization normally depends on several atomic parameters and, most importantly, on atomic coordinates. The large number of adjustable parameters (typically at least three times the number of atoms in the model) gives rise to a very complicated target function. This, in turn, produces what is known as the multiple minima problem: the target function contains many local minima in addition to the global minimum, and this tends to defeat gradient-descent optimization techniques such as conjugate gradient or least-squares methods (Press *et al.*, 1986). These methods are unable to sample molecular conformations thoroughly enough to find the optimal model if the starting one is far from the correct structure.

The challenges of crystallographic refinement arise not only from the high dimensionality of the parameter space, but also from the phase problem. For new crystal structures, initial electron-density maps must be computed from a combination of observed diffraction amplitudes and experimental phases, where the latter are typically of poorer quality and/or at a lower resolution than the former. A different problem arises when structures are solved by molecular replacement (Hoppe, 1957; Rossmann & Blow, 1962), which uses a similar structure as a search model to calculate initial phases. In this case, the resulting electron-density maps can be severely 'model-biased', that is, they sometimes seem to confirm the existence of the search model without providing clear evidence of actual differences between it and the true crystal structure. In both cases, initial atomic models usually contain significant errors and require extensive refinement.

Simulated annealing (Kirkpatrick *et al.*, 1983) is an optimization technique particularly well suited to overcoming the multiple minima problem. Unlike gradient-descent methods, simulated annealing can cross barriers between minima and, thus, can explore a greater volume of the parameter space to find better models (deeper minima). Following its introduction to crystallographic refinement (Brünger *et al.*, 1987), there have been major improvements of the original method in four principal areas: the measure of model quality, the search of the parameter space, the target function and the modelling of conformational variability.

For crystallographic refinement, the introduction of cross validation and the free *R* value (Brünger, 1992) has significantly reduced the danger of overfitting the diffraction data during refinement. Cross validation also produces more realistic coordinate-error estimates based on the Luzzati or σ_A methods (Kleywegt & Brünger, 1996). The complexity of the conformational space has been reduced by the introduction of torsion-angle refinement methods (Diamond, 1971; Rice & Brünger, 1994), which decrease the number of adjustable parameters that describe a model approximately tenfold. The target function has been improved by using a maximum-likelihood approach which takes into account model error, model incompleteness and errors in the experimental data (Bricogne, 1991; Pannu & Read, 1996). Cross validation of parameters for the maximum-likelihood target function was essential in order to obtain better results than with conventional target functions (Pannu & Read, 1996; Adams *et al.*, 1997; Read, 1997). Finally, the sampling power of simulated annealing has been used for exploring the molecule's conformational space in cases where the molecule undergoes dynamic motion or exhibits static disorder (Kuriyan *et al.*, 1991; Burling & Brünger, 1994; Burling *et al.*, 1996).

18.2.2. Cross validation

Cross validation (Brünger, 1992) plays a fundamental role in the maximum-likelihood target functions described below. A few remarks about this method are therefore warranted (for reviews see Kleywegt & Brünger, 1996; Brünger, 1997). For cross validation, the diffraction data are divided into two sets: a large *working* set (usually comprising 90% of the data) and a complementary *test* set (comprising the remaining 10%). The diffraction data in the working set are used in the normal crystallographic refinement process, whereas the test data are not. The cross-validated (or 'free') *R* value computed with the test-set data is a more faithful indicator of model quality. It provides a more objective guide during the model building and refinement process than the conventional *R* value. It also ensures that introduction of additional parameters (*e.g.* water molecules, relaxation of noncrystallographic symmetry restraints, or multiconformer models) improves the quality of the model, rather than increasing overfitting.

Since the conventional *R* value shows little correlation with the accuracy of a model, coordinate-error estimates derived from the Luzzati (1952) or σ_A (Read, 1986) methods are unrealistically low. Kleywegt & Brünger (1996) showed that more reliable coordinate errors can be obtained by cross validation of the Luzzati or σ_A coordinate-error estimates. An example is shown in Fig. 18.2.2.1 using the crystal structure and diffraction data of penicillopepsin (Hsu *et al.*, 1977). At 1.8 Å resolution, the model has an estimated coordinate error of ∼0.2 Å as assessed by multiple independent refinements. As the resolution of the diffraction data is artificially truncated and the model re-refined, the coordinate error (assessed by the atomic root-mean-square difference to the refined model at 1.8 Å resolution) increases monotonically. The conventional *R* value improves as the resolution decreases and the quality of the model worsens. Consequently, coordinate-error estimates do not display the correct behaviour either: the error estimates are approximately constant, regardless of the resolution and actual coordinate error of the models. However, when cross validation is used (*i.e.*, the test reflections are used to compute the estimated coordinate errors),

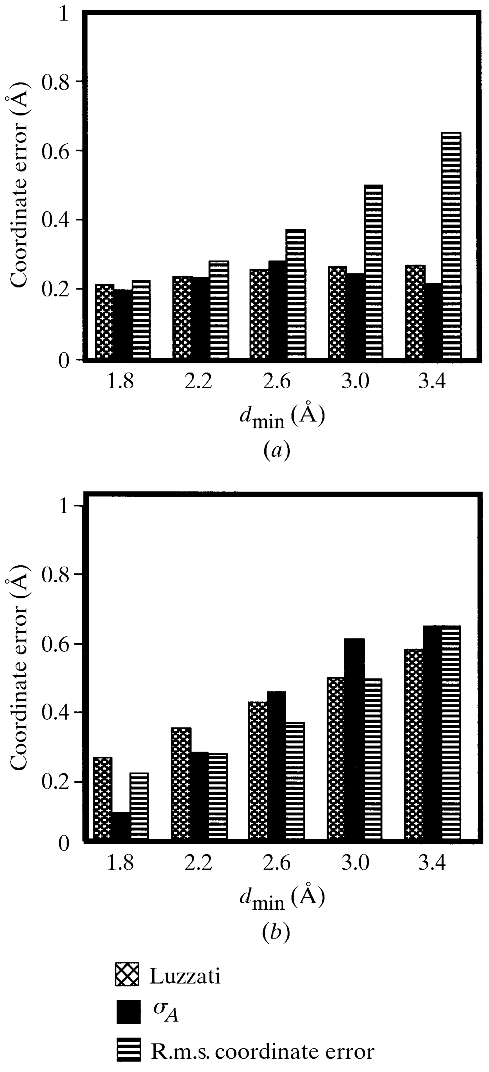

Figure 18.2.2.1

Effect of resolution on coordinate-error estimates: accuracy as a function of resolution. Refinements were begun with the crystal structure of penicillopepsin (Hsu *et al.*, 1977) with water molecules omitted and with uniform temperature factors. The low-resolution limit was set to 6 Å. Inclusion of all low-resolution diffraction data does not change the conclusions (Adams *et al.*, 1997). The penicillopepsin diffraction data were artificially truncated to the specified high-resolution limit. Each refinement consisted of simulated annealing using a Cartesian-space slow-cooling protocol starting at 2000 K, overall B-factor refinement and individual restrained B-factor refinement. All refinements were carried out with 10% of the diffraction data randomly omitted for cross validation. (*a*) Coordinate-error estimates of the refined structures using the methods of Luzzati (1952) and Read (1986). All observed diffraction data were used, *i.e.* no cross validation was performed. The actual coordinate errors (r.m.s. differences to the original crystal structure) are shown for comparison. (*b*) Cross-validated coordinate-error estimates. The test set was used to compute the coordinate-error estimates (Kleywegt & Brünger, 1996).

the results are much better: the cross-validated errors are close to the actual coordinate error, and they show the correct trend as a function of resolution (Fig. 18.2.2.1).

18.2.3. The target function

Crystallographic refinement is a search for the global minimum of the target

$$E = E_{\text{chem}} + w_{\text{X-ray}} E_{\text{X-ray}} \qquad (18.2.3.1)$$

as a function of the parameters of an atomic model, in particular, atomic coordinates. E_{chem} comprises empirical information about chemical interactions; it is a function of all atomic positions, describing covalent (bond lengths, bond angles, torsion angles, chiral centres and planarity of aromatic rings) and non-bonded (intramolecular as well as intermolecular and symmetry-related) interactions (Hendrickson, 1985). $E_{\text{X-ray}}$ is related to the difference between observed and calculated data, and $w_{\text{X-ray}}$ is a weight appropriately chosen to balance the gradients (with respect to atomic parameters) arising from the two terms.

18.2.3.1. X-ray diffraction data versus model

The traditional form of $E_{\text{X-ray}}$ consists of the crystallographic residual, E^{LSQ}, defined as the sum over the squared differences between the observed ($|\mathbf{F}_o|$) and calculated ($|\mathbf{F}_c|$) structure-factor amplitudes for a particular atomic model:

$$E_{\text{X-ray}} = E^{\text{LSQ}} = \sum_{hkl\in\text{working set}} (|\mathbf{F}_o| - k|\mathbf{F}_c|)^2, \qquad (18.2.3.2)$$

where hkl are the indices of the reciprocal-lattice points of the crystal and k is a relative scale factor.

Minimization of E^{LSQ} can produce improvement in the atomic model, but it can also accumulate systematic errors in the model by fitting noise in the diffraction data (Silva & Rossmann, 1985). The least-squares residual is a limiting case of the more general maximum-likelihood theory and is only justified if the model is nearly complete and error-free. These assumptions may be violated during the initial stages of refinement. Improved targets for macromolecular refinement have been obtained using the more general maximum-likelihood formulation (Bricogne, 1991; Pannu & Read, 1996; Adams *et al.*, 1997; Murshudov *et al.*, 1997). The goal of the maximum-likelihood method is to determine the likelihood of the model, given estimates of the model's errors and those of the measured intensities.

A starting point for the maximum-likelihood formulation of crystallographic refinement is the Sim (1959) distribution, *i.e.*, the Gaussian conditional probability distribution of the 'true' structure factors, **F**, given a partial model with structure factors $\mathbf{F}_c$ and the model's error (Fig. 18.2.3.1) (Srinivasan, 1966; Read, 1986, 1990) (for simplicity we will only discuss the case of acentric reflections),

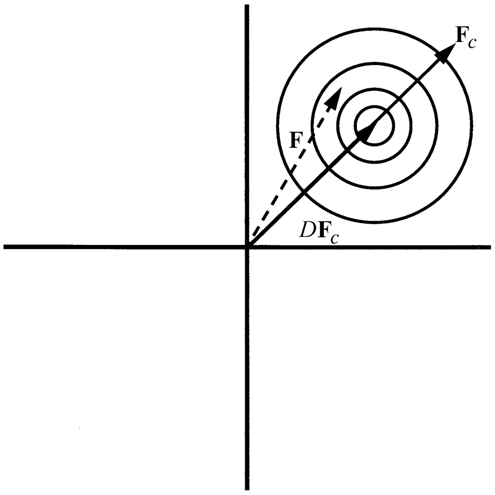

Figure 18.2.3.1

The Gaussian probability distribution forms the basis of maximum-likelihood targets in crystallographic refinement. The conditional probability of the true structure factor, **F**, given model structure factors, is a Gaussian in the complex plane [equation (18.2.3.3)]. The expected value of the probability distribution is $D\mathbf{F}_c$ with variance σ_Δ, where D and σ_Δ account for missing or incorrectly placed atoms in the model.

$$P_a(\mathbf{F};\mathbf{F}_c) = (1/\pi\varepsilon\sigma_\Delta^2)\exp[-(\mathbf{F} - D\mathbf{F}_c)^2/\varepsilon\sigma_\Delta^2], \qquad (18.2.3.3)$$

where σ_Δ is a parameter that incorporates the effect of the fraction of the asymmetric unit that is missing from the model and errors in the partial structure. Assuming a Wilson distribution of intensities, it can be shown that (Read, 1990)

$$\sigma_\Delta^2 = \langle|\mathbf{F}_o|^2\rangle - D^2\langle|\mathbf{F}_c|^2\rangle, \qquad (18.2.3.4)$$

where D is a factor that takes into account model error: it is unity in the limiting case of an error-free model and it is zero if no model is available (Luzzati, 1952; Read, 1986). For a complete and error-free model, σ_Δ therefore becomes zero, and the probability distribution, $P_a(\mathbf{F};\mathbf{F}_c)$, is infinitely sharp.

Taking measurement errors into account requires multiplication of equation (18.2.3.3) with an appropriate probability distribution (usually a conditional Gaussian distribution with standard deviation σ_o) of the observed structure-factor amplitudes ($|\mathbf{F}_o|$) around the 'true' structure-factor amplitudes ($|\mathbf{F}|$),

$$P_{\rm meas}(|\mathbf{F}_o|;|\mathbf{F}|). \qquad (18.2.3.5)$$

Prior knowledge of the phases of the structure factors can be incorporated by multiplying equation (18.2.3.3) with a phase probability distribution

$$P_{\rm phase}(\varphi) \qquad (18.2.3.6)$$

and rewriting equation (18.2.3.3) in terms of the structure-factor moduli and amplitudes of $\mathbf{F} = |\mathbf{F}|\exp(i\varphi)$.

The unknown variables $|\mathbf{F}|$ and φ in equations (18.2.3.3)–(18.2.3.5) have to be eliminated by integration in order to obtain the conditional probability distribution of the observed structure-factor amplitudes, given a partial model with errors, the amplitude measurement errors and prior phase information:

$$\begin{aligned}P_a(|\mathbf{F}_o|;\mathbf{F}_c) &= (1/\pi\varepsilon\sigma_\Delta^2)\textstyle\int {\rm d}\varphi\,{\rm d}|\mathbf{F}|;\ |\mathbf{F}|P_{\rm meas}(|\mathbf{F}_o|;|\mathbf{F}|)\\ &\quad\times P_{\rm phase}(\varphi)\exp\left\{-[|\mathbf{F}|\exp(i\varphi) - D\mathbf{F}_o]^2/\varepsilon\sigma_\Delta^2\right\}.\end{aligned} \qquad (18.2.3.7)$$

The likelihood, $\mathcal{L}$, of the model is defined as the joint probability distribution of the structure factors of all reflections in the working set. Assuming independent and uncorrelated structure factors, $\mathcal{L}$ is simply the product of the distributions in equation (18.2.3.7) for all reflections. Instead of maximizing the likelihood, it is more common to minimize the negative logarithm of the likelihood,

$$E_{\text{X-ray}} = \mathcal{L} = -\sum_{hkl\in\text{working set}}\log[P_a(|\mathbf{F}_o|;\mathbf{F}_c)]. \qquad (18.2.3.8)$$

Empirical estimates of σ_Δ [and D through equation (18.2.3.4)] can be obtained by minimizing $\mathcal{L}$ for a particular atomic model. It is generally assumed that σ_Δ and D show relatively little variation among neighbouring reflections. Accepting this assumption, σ_Δ and D can be estimated by considering narrow resolution shells of reflections and assuming that the two parameters are constant in these shells. Minimization of $\mathcal{L}$ can then be performed as a function of these constant shell parameters while keeping the atomic model fixed (Read, 1986, 1997). Alternatively, one can assume a two-term Gaussian model for σ_Δ (Murshudov *et al.*, 1997) and minimize $\mathcal{L}$ as a function of the Gaussian parameters. Note that individual atomic B factors are taken into account by the calculated model structure factors ($\mathbf{F}_c$).

This empirical approach to estimate σ_Δ and D requires occasional recomputation of these values as the model improves. Refinement methods that improve the model structure factors, $\mathbf{F}_c$, will therefore have a beneficial effect on σ_Δ and D. Better estimates of these values will then enhance the next refinement cycle. Thus, powerful optimization methods and maximum-likelihood targets are expected to interact in a synergistic fashion (*cf.* Fig. 18.2.5.1). Structure-factor averaging of multi-start refinement models can provide another layer of improvement by producing a better description of $\mathbf{F}_c$ if the model shows significant variability due to errors or intrinsic flexibility (see below).

In order to achieve an improvement over the least-squares residual [equation (18.2.3.2)], cross validation was found to be essential (Pannu & Read, 1996; Adams *et al.*, 1997) for the estimation of model incompleteness and errors (σ_Δ and D). Since the test set typically contains only 10% of the diffraction data, these cross-validated quantities can show significant statistical fluctuations as a function of resolution. In order to reduce these fluctuations, Read (1997) devised a smoothing method by applying restraints to σ_A values between neighbouring resolution shells where

$$\sigma_A = \left[1 - (\sigma_\Delta/\langle|\mathbf{F}_o|^2\rangle)\right]^{1/2}. \qquad (18.2.3.9)$$

Pannu & Read (1996) have developed an efficient Gaussian approximation of equation (18.2.3.7) in cases of no prior phase information, termed the 'MLF' target function. In the limit of a perfect model (*i.e.* $\sigma_\Delta = 0$ and $D = 1$), MLF reduces to the traditional least-squares residual [equation (18.2.3.2)] with $1/\sigma_o^2$ weighting. In the case of prior phase information, the integration over the phase angles has been carried out numerically in equation (18.2.3.7), termed the 'MLHL' target (Pannu *et al.*, 1998). A maximum-likelihood function which expresses equation (18.2.3.7) in terms of observed intensities has also been developed, termed 'MLI' (Pannu & Read, 1996).

18.2.3.2. *A priori chemical information*

The parameters for the covalent terms in $E_{\rm chem}$ [equation (18.2.3.1)] can be derived from the average geometry and (r.m.s.) deviations observed in a small-molecule database. Extensive statistical analyses were undertaken for the chemical moieties of proteins (Engh & Huber, 1991) and polynucleotides (Parkinson *et al.*, 1996) using the Cambridge Structural Database (Allen *et al.*, 1983). Analysis of the ever-increasing number of atomic resolution macromolecular crystal structures will no doubt cause some modifications of these parameters in the future.

It is common to use a purely repulsive quartic function ($E_{\rm repulsive}$) for the non-bonded interactions that are included in $E_{\rm chem}$ (Hendrickson, 1985):

$$E_{\rm repulsive} = \sum_{ij}[(cR_{ij}^{\min})^n - R_{ij}^n]^m, \qquad (18.2.3.10)$$

where R_{ij} is the distance between two atoms i and j, $R_{ij}^{\min}$ is the van der Waals radius for a particular atom pair ij, $c \leq 1$ is a constant that is sometimes used to reduce the radii, and $n = 2$, $m = 2$ or $n = 1$, $m = 4$. van der Waals attraction and electrostatic interactions are usually not included in crystallographic refinement. These simplifications are valid since the diffraction data contain information that is able to produce atomic conformations consistent with actual non-bonded interactions. In fact, atomic resolution crystal structures can be used to derive parameters for electrostatic charge distributions (Pearlman & Kim, 1990).

18.2.4. Searching conformational space

Annealing denotes a physical process wherein a solid is heated until all particles randomly arrange themselves in a liquid phase and is then cooled slowly so that all particles arrange themselves in the lowest energy state. By formally defining the target, E [equation (18.2.3.1)], to be the equivalent of the potential energy of the system, one can simulate such an annealing process (Kirkpatrick *et al.*, 1983). There is no guarantee that simulated annealing will find the global minimum (Laarhoven & Aarts, 1987). However, compared to conjugate-gradient minimization, where search directions must follow the gradient, simulated annealing achieves more optimal solutions by allowing motion against the gradient (Kirkpatrick *et al.*, 1983). The likelihood of *uphill* motion is determined by a control parameter referred to as *temperature*. The higher the temperature, the more likely it is that simulated annealing will overcome barriers (Fig. 18.2.4.1). It should be noted that the simulated-annealing temperature normally has no physical meaning and merely determines the likelihood of overcoming barriers of the target function in equation (18.2.3.1).

The simulated-annealing algorithm requires a mechanism to create a Boltzmann distribution at a given temperature, T, and an annealing schedule, that is, a sequence of temperatures $T_1 \geq T_2 \geq \ldots \geq T_l$ at which the Boltzmann distribution is computed. Implementations differ in the way they generate a transition, or move, from one set of parameters to another that is consistent with the Boltzmann distribution at a given temperature. The two most widely used methods are Metropolis Monte Carlo (Metropolis *et al.*, 1953) and molecular dynamics (Verlet, 1967) simulations. For X-ray crystallographic refinement, molecular dynamics has proven extremely successful (Brünger *et al.*, 1987) because it limits the search to physically reasonable 'moves'.

18.2.4.1. Molecular dynamics

A suitably chosen set of atomic parameters can be viewed as generalized coordinates that are propagated in time by the classical equations of motion (Goldstein, 1980). If the generalized coordinates represent the x, y, z positions of the atoms of a molecule, the classical equations of motion reduce to the familiar Newton's second law:

$$m_i \frac{\partial^2 \mathbf{r}_i}{\partial t^2} = -\nabla_i E. \qquad (18.2.4.1)$$

The quantities m_i and $\mathbf{r}_i$ are, respectively, the mass and coordinates of atom i, and E is given by equation (18.2.3.1). The solution of the partial differential equations (18.2.4.1) can be achieved numerically using finite-difference methods (Verlet, 1967; Abramowitz & Stegun, 1968). This approach is referred to as molecular dynamics.

Initial velocities for the integration of equation (18.2.4.1) are usually assigned randomly from a Maxwell distribution at the appropriate temperature. Assignment of different initial velocities will generally produce a somewhat different structure after simulated annealing. By performing several refinements with different initial velocities, one can therefore improve the chances of success of simulated-annealing refinement. Furthermore, this improved sampling can be used to study discrete disorder and conformational variability, especially when using torsion-angle molecular dynamics (see below).

Although Cartesian (*i.e.* flexible bond lengths and bond angles) molecular dynamics places restraints on bond lengths and bond angles [through E_{chem}, equation (18.2.3.1)], one might want to implement these restrictions as constraints, *i.e.*, fixed bond lengths and bond angles (Diamond, 1971). This is supported by the observation that the deviations from ideal bond lengths and bond angles are usually small in macromolecular X-ray crystal structures. Indeed, fixed-length constraints have been applied to crystallographic refinement by least-squares minimization (Diamond, 1971). It is only recently, however, that efficient and robust algorithms have become available for molecular dynamics in torsion-angle space (Bae & Haug, 1987, 1988; Jain *et al.*, 1993; Rice & Brünger, 1994). We chose an approach that retains the Cartesian-coordinate formulation of the target function and its derivatives with respect to atomic coordinates, so that the calculation remains relatively straightforward and can be applied to any macromolecule or their complexes (Rice & Brünger, 1994). In this formulation, the expression for the acceleration becomes a function of positions and velocities. Iterative equations of motion for constrained dynamics in this formulation can be derived and solved by finite-difference methods (Abramowitz & Stegun, 1968). This method is numerically very robust and has a significantly increased radius of convergence in crystallographic refinement compared to Cartesian molecular dynamics (Rice & Brünger, 1994).

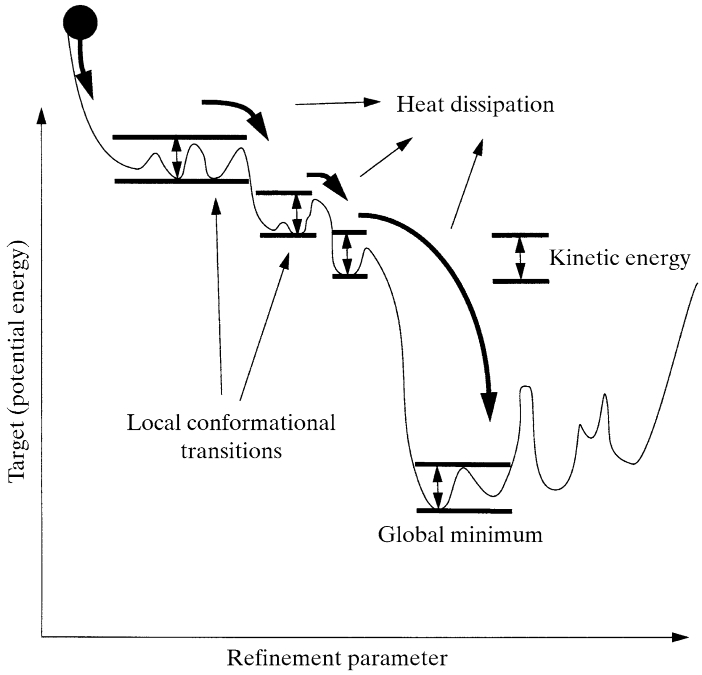

Figure 18.2.4.1
Illustration of simulated annealing for minimization of a one-dimensional function. The kinetic energy of the system (a 'ball' rolling on the one-dimensional surface) allows local conformational transitions with barriers smaller than the kinetic energy. If a larger drop in energy is encountered, the excess kinetic energy is dissipated. It is thus unlikely that the system can climb out of the global minimum once it has reached it.

18.2.4.2. Temperature control

Simulated annealing requires the control of the temperature during molecular dynamics. The current temperature of the simulation (T_{curr}) is computed from the kinetic energy

$$E_{\text{kin}} = \sum_i^n \tfrac{1}{2} m_i \left(\frac{\partial r_i}{\partial t} \right)^2 \qquad (18.2.4.2)$$

of the molecular-dynamics simulation,

$$T_{\text{curr}} = 2E_{\text{kin}}/3nk_B. \qquad (18.2.4.3)$$

Here, n is the number of atoms, m_i is the mass of the atom and k_B is Boltzmann's constant. One commonly used approach to control the temperature of the simulation consists of coupling the equations of motion to a heat bath through a 'friction' term (Berendsen *et al.*, 1984). Another approach is to rescale periodically the velocities in order to match $T_{\rm curr}$ with the target temperature.

18.2.4.3. Annealing schedules

The simulated-annealing temperature needs to be high enough to allow conformational transitions, but not so high that the model moves too far away from the correct structure. The optimal temperature for a given starting structure is a matter of trial and error. Starting temperatures that work for the average case have been determined for a variety of simulated-annealing protocols (Brünger, 1988; Adams *et al.*, 1997). However, it might be worth trying a different temperature if a particularly difficult refinement problem is encountered. In particular, significantly higher temperatures are attainable using torsion-angle molecular dynamics. Note that each simulated-annealing refinement is subject to 'chance' by using a random-number generator to generate the initial velocities. Thus, multiple simulated annealing runs can be carried out in order to increase the success rate of the refinement. The best structure(s) (as determined by the free *R* value) among a set of refinements using different initial velocities and/or temperatures can be taken for further refinement or structure-factor averaging (see below).

The annealing schedule can, in principle, be any function of the simulation step (or 'time' domain). The two most commonly used protocols are linear slow-cooling or constant-temperature followed by quenching. A slight advantage is obtained with slow cooling (Brünger *et al.*, 1990). The duration of the annealing schedule is another parameter. Too short a protocol does not allow sufficient sampling of conformational space. Too long a protocol may waste computer time, since it is more efficient to run multiple trials than one long refinement protocol (unpublished results).

18.2.4.4. An intuitive explanation of simulated annealing

The goal of any optimization problem is to find the global minimum of a target function. In the case of crystallographic refinement, one searches for the conformation or conformations of the molecule that best fit the diffraction data and that simultaneously maintain reasonable covalent and non-covalent interactions. Simulated-annealing refinement has a much larger radius of convergence than conjugate-gradient minimization (see below). It must, therefore, be able to find a lower minimum of the target *E* [equation (18.2.3.1)] than the local minimum found by simply moving along the negative gradient of *E*.

It is most easy to visualize this property of simulated annealing in the case of a one-dimensional problem, where the goal is to find the global minimum of a function with multiple minima (Fig. 18.2.4.1). An intuitive way to understand a molecular-dynamics simulation is to envisage a ball rolling on this one-dimensional surface. When the ball is far from the global minimum, it gains a certain momentum which allows it to cross barriers of the target function [equation (18.2.4.3)]. Slow-cooling temperature control ensures that the ball will eventually reach the global minimum rather than just bouncing across the surface. The initial temperature must be large enough to overcome smaller barriers, but low enough to ensure that the system will not escape the global minimum if it manages to arrive there.

While temperature itself is a global parameter of the system, temperature fluctuations arise principally from local conformational transitions, for example, from an amino-acid side chain falling into the correct orientation. These local changes tend to lower the value of the target *E*, thus increasing the kinetic energy, and hence the temperature, of the system. Once the temperature control has removed this excess kinetic energy through 'heat dissipation', the reverse transition is very unlikely, since it would require a localized increase in kinetic energy where the conformational change occurred in the first place (Fig. 18.2.4.1). Temperature control maintains a sufficient amount of kinetic energy to allow local conformational corrections, but does not supply enough to allow escape from the global minimum. This explains the observation that, on average, the agreement with the diffraction data will improve, rather than worsen, with simulated annealing.

18.2.5. Examples

Many examples have shown that simulated-annealing refinement starting from initial models (obtained by standard crystallographic techniques) produces significantly better final models compared to those produced by least-squares or conjugate-gradient minimization (Brünger *et al.*, 1987; Brünger, 1988; Fujinaga *et al.*, 1989; Kuriyan *et al.*, 1989; Rice & Brünger, 1994; Adams *et al.*, 1997). In another realistic test case (Adams *et al.*, 1999), a series of models for the aspartic proteinase penicillopepsin were generated from homologous structures present in the Protein Data Bank. The sequence identity among these structures ranged from 100% to 25%, thus providing a set of models with increasing coordinate error compared to the refined structure of penicillopepsin. These models, after truncation of all

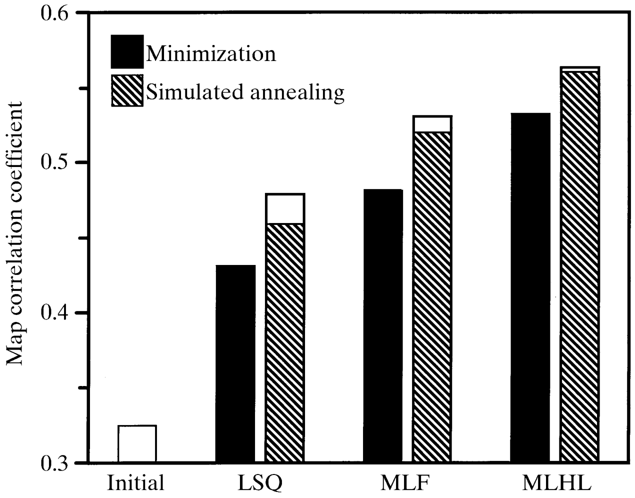

Figure 18.2.5.1
Simulated annealing produces better models than extensive conjugate-gradient minimization. Map correlation coefficients were computed before and after refinement against the native penicillopepsin diffraction data (Hsu *et al.*, 1977) for the polyalanine model derived from Rhizopuspepsin (Suguna *et al.*, 1987, PDB code 2APR). Correlation coefficients are between σ_A-weighted maps calculated from each model and from the published penicillopepsin structure. The observed penicillopepsin diffraction data were in space group *C*2 with cell dimensions $a = 97.37$, $b = 46.64$, $c = 65.47$ Å and $\beta = 115.4°$. All refinements were carried out using diffraction data from the lowest-resolution limit of 22.0 Å up to 2.0 Å. The MLHL refinements used single isomorphous phases from a $K_3UO_2F_5$ derivative of the penicillopepsin crystal structure, which covered a resolution range of 22.0 Å to 2.8 Å. Simulated-annealing refinements were repeated five times with different initial velocities. The numerical averages of the map correlation coefficients for the five refinements are shown as hashed bars. The best map correlation coefficients from simulated annealing are shown as white bars.

residues to alanine, were all used as search models in molecular replacement against the native penicillopepsin diffraction data. In all cases, the correct placement of the model in the penicillopepsin unit cell was found.

Both conjugate-gradient minimization and simulated annealing were carried out in order to compare the performance of the $E^{\rm LSQ}$ least-squares residual [equation (18.2.3.2)], MLF (the maximum-likelihood target using amplitudes) and MLHL (the maximum-likelihood target using amplitudes and experimental phase information). In the latter case, phases from single isomorphous replacement (SIR) were used. A very large number of conjugate-gradient cycles were carried out in order to make the computational requirements equivalent for both minimization and simulated annealing. The conjugate-gradient minimizations were converged, *i.e.* there was no change when further cycles were carried out.

For a given target function, simulated annealing always outperformed minimization (Fig. 18.2.5.1). For a given starting model, the maximum-likelihood targets outperformed the least-squares-residual target for both minimization and simulated annealing, producing models with lower phase errors and higher map correlation coefficients when compared with the published penicillopepsin crystal structure (Fig. 18.2.5.1). This improvement is illustrated in σ_A-weighted electron-density maps obtained from the resulting models (Fig. 18.2.5.2). The incorporation of experimental phase information further improved the refinement significantly despite the ambiguity in the SIR phase probability distributions. Thus, the most efficient refinement will make use of simulated annealing and phase information in the MLHL maximum-likelihood target function.

Cross validation is essential in the calculation of the maximum-likelihood target (Kleywegt & Brünger, 1996; Pannu & Read, 1996; Adams *et al.*, 1997). Maximum-likelihood refinement without cross validation gives much poorer results, as indicated by higher free R values, $R_{\rm free} - R$ differences and phase errors (Adams *et al.*, 1997). It should be noted that the final normal R value is in general increased, compared to refinements with the least-squares target, when using the cross-validated maximum-likelihood formulation. This is a consequence of the reduction of overfitting by this method.

18.2.6. Multi-start refinement and structure-factor averaging

Multiple simulated-annealing refinements starting from the same model, termed 'multi-start' refinement, will generally produce somewhat different structures. Even well refined structures will show some variation consistent with the estimated coordinate error of the model (*cf.* results for 1.8 Å resolution in Fig. 18.2.2.1). More importantly, the poorer the model, the more variation is observed (Brünger, 1988). Some of the models resulting from multi-start refinement may be better than others, for example, as judged by the free R value. Thus, if computer time is available, multi-start refinement has several advantages. A more optimal single model than that produced by a single simulated-annealing calculation can usually be obtained. Furthermore, each separate model coming from a multi-start refinement fits the data slightly differently. This could be the result of intrinsic flexibility in the molecule (see below) or the result of model-building error. Regions in the starting model that contain significant errors often show increased variability after multi-start refinement, and a visual inspection of the ensemble of models produced can be helpful in identifying these incorrectly modelled regions.

To better identify the correct conformation, structure factors from each of the models can be averaged (Rice *et al.*, 1998). This averaging tends to reduce the effect of local errors (noise) that are presumably different in each member of the family. The average structure factor can produce phases that contain less model bias than phases computed from a single model. It should also produce better estimates of σ_Δ and D for maximum-likelihood targets and for σ_A-weighted electron-density maps, because $\mathbf{F}_c$ is used in the computation of these parameters [equation (18.2.3.7)]. Because it is inherently a noise-reducing technique, multi-start refinement followed by structure-factor averaging should be most useful in situations where there is significant noise, namely when the data-to-parameter ratio is low (*e.g.* if only moderate-resolution diffraction data are available).

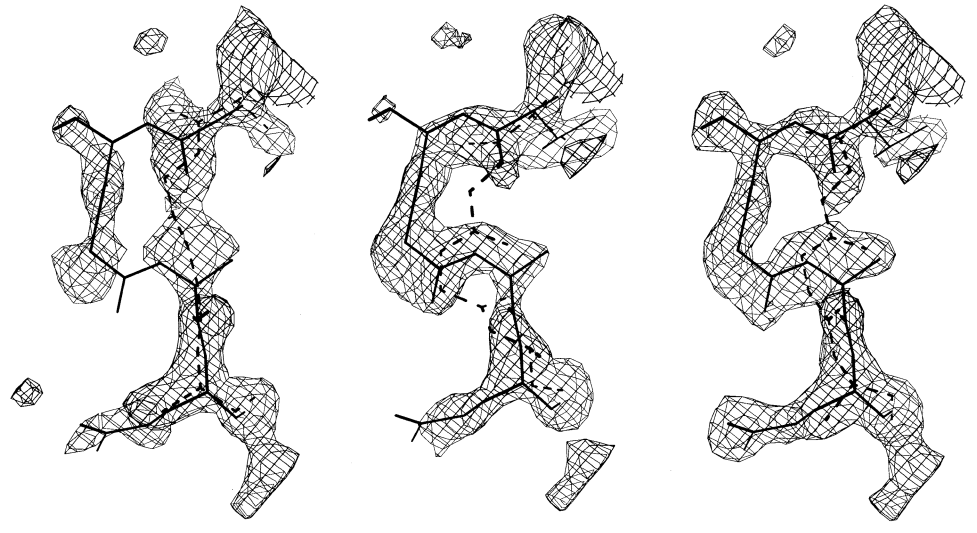

Figure 18.2.5.2
Maximum-likelihood targets significantly decrease model bias in simulated-annealing refinement. σ_A-weighted electron-density maps contoured at 1.25σ for models from simulated-annealing refinement with different targets are shown. Residues 233 to 237 are shown for the published penicillopepsin crystal structure (Hsu *et al.*, 1977) as solid lines, and for the model with the lowest free R value from five independent refinements as dashed lines.

18.2.7. Ensemble models

In cases of conformational variability or discrete disorder, there is not one single correct solution to the global minimization of equation (18.2.3.1). Rather, the X-ray diffraction data represent a spatial and temporal average over all conformations that are assumed by the molecule. Ensembles of structures, which are simultaneously refined against the observed data, may thus be a more appropriate description of the diffraction data. This has been used for some time when alternate conformations are modelled locally. Alternate conformations can be generalized to global conformations (Gros *et al.*, 1990; Kuriyan *et al.*, 1991; Burling & Brünger, 1994), *i.e.*, the model is duplicated n-fold, the calculated structure factors corresponding to each copy of the model are summed, and this composite structure factor is refined against the observed

X-ray diffraction data. Each member of the family is chemically 'invisible' to all other members. The optimal number, n, can be determined by cross validation (Burling & Brünger, 1994; Burling *et al.*, 1996).

An advantage of a multi-conformer model is that it directly incorporates many possible types of disorder and motion (global disorder, local side-chain disorder, local wagging and rocking motions). Furthermore, it can be used to detect automatically the most variable regions of the molecule by inspecting the atomic r.m.s. difference around the mean as a function of residue number. Thermal factors of single-conformer models may sometimes be misleading because they underestimate the degree of motion or disorder (Kuriyan *et al.*, 1986), and, thus, the multiple-conformer model can be a more faithful representation of the diffraction data. A disadvantage of the multi-conformer model is that it introduces many more parameters in the refinement.

Although there are some similarities between averaging structure factors of individually refined structures and performing multi-conformer refinement, there are also fundamental differences. For example, multi-start averaging seeks to improve the calculated electron-density map by averaging out the noise present in the individual models, each of which is still a good representation of the diffraction data. This method is most useful at the early stages of refinement when the model still contains errors. In contrast, multi-conformer refinement seeks to create an ensemble of structures at the final stages of refinement which, taken together, best represent the data. It should be noted that each individual conformer of the ensemble does not necessarily remain a good description of the diffraction data, since the whole ensemble is refined against the data. Clearly, multi-conformer refinement requires a high observable-to-parameter ratio.

18.2.8. Conclusions

Simulated annealing has dramatically improved the efficiency of crystallographic refinement. A case in point is the combination of torsion-angle molecular dynamics with cross-validated maximum-likelihood targets. These two independent developments interact synergistically to produce less model bias than any other method to date. The combined method dramatically increases the radius of convergence, allowing the productive refinement of poor initial models, *e.g.* those obtained by weak molecular-replacement solutions (Rice & Brünger, 1994; Adams *et al.*, 1997, 1999).

Simulated annealing can also be used to provide new physical insights into molecular function which may depend on conformational variability. The sampling characteristics of simulated annealing allow the generation of multi-conformer models that can represent molecular motion and discrete disorder, especially when combined with the acquisition of high-quality data (Burling *et al.*, 1996). Thus, simulated annealing is also a stepping stone towards development of improved models of macromolecules in solution and in the crystalline state.

The computational developments discussed in this review are implemented in the software suite *Crystallography & NMR System* (Brunger *et al.*, 1998). A pre-release of the software suite is available upon request.

Chapter 18.3. Structure quality and target parameters

R. A. Engh and R. Huber

18.3.1. Purpose of restraints

> Believe statistics! Shun bias! – these, we see, are two materially different laws. (Adapted from William James.) A wise man, therefore, proportions his restraints to the evidence. (Adapted from David Hume.)

If we could adequately measure the complex diffuse scattering function of an X-ray beam from a single macromolecular structure to arbitrary resolution, we could, given an accurate model for X-ray scattering, calculate a measurement-time-averaged electron-density distribution for that structure independent of most model assumptions. Alternatively, if we knew the potential energy for the system accurately as a function of all relevant parameters, classical and non-classical, and had the computational power to analyse the function appropriately, we could model the same distribution. If both experiment and theory were accessible at these extremes, the available information would be redundant and could be used together in arbitrary ways. Of course, both experiment and theory are limited far below these extremes, and the researcher must consider what information is available in order to address the pertinent protein-structure question in the most appropriate way.

The most general theoretical assumptions used to interpret experimentally determined X-ray reflections typically include the spherical symmetry of scattering functions centred at nuclei, harmonicity (and isotropy) of deviations about average positions, infinity of a crystal lattice of identical unit cells and so on. While the majority of structures determined to date share a standard set of assumptions, significant alternatives have been proposed, such as, for example, the modelling of motion with normal-mode analyses instead of harmonic temperature factors (Kidera *et al.*, 1994). Any significant change in the set of assumptions used in structure determination must be expected to leave its mark on the statistical properties of the structure.

Besides the necessity of general model assumptions for structure determination, there is the simple necessity to supplement the measured reflection data with additional sources of information to improve the ratio of experimental observables to model parameters. For example, a crystal of a protein with some 3000 atoms that diffracts to a moderate resolution of 2.5 Å might produce some 14 000 measurable unique reflections. In this case, fitting a model that includes three Cartesian coordinates and a temperature factor for each atom (12 000 parameters) is effectively underdetermined when considering experimental error. The solution is either to reduce the number of parameters by introducing constraints to the model, or to increase the number of effective observations by using additional restraints in the structure determination.

18.3.1.1. *Utility of restraints: protein/special geometries*

One set of restraints arises from the expectation that the macromolecular structure should be chemically reasonable, that is, it should reflect the geometries required by chemical physics. This restricts especially values of bond lengths, bond angles, planarity and improper dihedral angles. Additional restriction comes from the expectation that these values should most closely conform to structures determined by the same experimental method and corresponding model assumptions. There are now two sources of structural information of sufficient quality for use as restraints in structure refinement: chemical fragments from the Cambridge Structural Database (CSD) and the very high resolution protein structures that can be refined without recourse to restraining parameters (Longhi *et al.*, 1998; Dauter *et al.*, 1997). Restraints derived from the CSD have come into widespread use for protein (Engh & Huber, 1991; Brünger, 1993; Priestle, 1994) and nucleic acid (Parkinson *et al.*, 1996) refinement; since their derivation, the database has grown from some 80 000 structures to around 200 000. The number of very high resolution protein structures solved has also increased to include dozens of structures (or thousands of chemical fragments). Chemical-fragment geometries can be studied using either or both sets of structures.

The optimal choice of restraints to use depends on the character and expected use of the refined structure. For example, the quality of comparative studies (Kleywegt & Jones, 1998) is enhanced by standardized refinement conditions, removing at least one source of systematic variation (*e.g.* Laskowski, Moss & Thornton, 1993), although effects from individual crystals and data collection and processing remain. On the other hand, a structure with an unusual chemical environment might require a tailored parameterization scheme to study the effects of this environment. Such cases might occur, for example, at enzyme active sites, where bound ligands may be distorted toward intermediate geometries (Bürgi & Dubler-Steudle, 1988).

18.3.1.2. *Risk of restraints: bias, lack of cross validation*

As an alternative to implementation as restraints, statistical information from known structures provides an independent check of structural integrity. However, the more information which is used for restraints, the less is available for such cross validation. For example, the use of a force field in protein refinement that strictly enforces a physical distribution of the protein backbone φ–ψ angles of the Ramachandran plot would transfer error-induced strain into other degrees of freedom while eliminating a Ramachandran analysis as a tool for judging protein quality (Hooft *et al.*, 1997). There is an additional risk associated with the intentional introduction of bias into protein refinement: Restraining a model to conform to known structures is in error if the structure is unique in some way and therefore should *not* conform to these structures, or if there is erroneous bias in the set of structures from which the restraints were derived. Furthermore, the bias may be exaggerated, especially if the biased feature is so probable that deviations are considered suspect. This can be seen, for example, in the increasing frequency of *cis*-prolines as protein-structure resolution increases (Stewart *et al.*, 1990): when there is uncertainty in lower-resolution structures, the more probable *trans*-prolines are preferentially chosen in model building, exaggerating their frequency.

18.3.2. Formulation of refinement restraints

A priori information regarding protein structure can be used in two fundamental ways: as constraints by fixing parameters to target values, or as restraints by allowing limited deviation from target values. The two methods differ fundamentally when counting the total number of degrees of freedom (important, for example, when thermodynamic quantities of simulations are considered), but both improve the observation-to-parameter ratio (constraints reduce parameters, restraints increase observations). In this chapter, we focus on the use of restraints.

A common form of restraint is an energy function parameterized to represent a conformational energy of a protein, driving the refinement toward a low-energy conformation but allowing reasonable deviations from it. Strictly, however, protein-structure refinement involves fitting model parameters to data measured from the ensemble of structures in the crystal; the model parameters should reflect ensemble properties rather than conformational energies of a single protein. This distinction may be subtle but it is statistically significant, particularly since the models themselves are simplified. For example, if the protein structure to be refined is modelled as a static structure with harmonic vibrations, then systematic errors could be expected if bond vibrations include significant anharmonicity. The systematically shortened C—H bonds of high-resolution X-ray crystal structures relative to those from neutron diffraction studies also show the systematic error involving the strictly erroneous approximation that scattering functions are spherically symmetric and centred at nuclei. These examples illustrate parameter problems that can in principle be minimized by correcting the refinement model, such as with the application of force-field restraints to an ensemble of structures, the addition of a statistically derived shift to proton positions, anisotropic scattering functions *etc.*

The 'stiffness' of the restraints should reflect the degree of confidence in the restraints. Here it is possible to distinguish different kinds of confidence, depending on the type of restraint used. The use of a conformational energy function as a refinement target function reflects the expectation that the magnitude of true deviations from the energy minima are related to the slopes of the physical energy potential surface; 'confidence' for bond lengths can thus be estimated from their vibration constants. An alternative approach is to derive target values from a database of independently determined structures. Distributions of parameter values derived from such databases have, in principle, arbitrary functional forms; a series expansion delivers the common descriptors of mean, variance, skew and so forth. The relatedness of the database to the system to be restrained determines how closely the distribution in the database should reflect the distribution in the restrained system. For proteins, it has seemed reasonable to expect that bond and angle parameters should share similar mean and sample variance distributions.

18.3.2.1. Choice of properties for restraint

Standard refinement procedures usually include the use of harmonic restraints of bond lengths, bond angles, planarity and 'improper' dihedrals, which, along with nuclear repulsions, comprise the 'hardest' restraints. Other geometric properties, such as dihedral angles, electrostatic interactions, Ramachandran energies *etc.*, can contribute further information to the refinement; these softer restraints can either distort the structure if weighted too strongly, or not contribute significantly to the refinement if weighted too weakly. Further, the softer restraints may be more useful as statistical parameters for judging the quality of a structure than as refinement parameters themselves. Particular care should be taken when refining with significant electrostatic energies: the forces have significant effects over long ranges, are usually based on simplified polarizability models and usually arise from assumptions of standard intrinsic pK_a values.

18.3.2.2. Simple derivation of force constants from parameter distributions

For a given distribution of parameter values, we take the average as the target value. If the choice of fragment geometries gives a distribution that corresponds to the varieties in the refinement problems, restraints should be applied to allow a similar range of freedom. In general, Gaussian distributions are assumed (with some obvious checks to avoid bimodal distributions) and are not corrected for non-orthogonality when parameters are introduced. If the refinement program uses a least-squares minimization method, the statistical mean and variance values can be used as tabulated. If an energy-function target is used, the variance values may be converted to force constants k defined by $E = k(\mathrm{d}x)^2$ by equating the Boltzmann probability, $\exp(-\mathrm{d}E/bT) = \exp[-k(\mathrm{d}x)^2/bT]$, with the Gaussian distribution function, $\exp[-(\mathrm{d}x)^2/(2\sigma^2)]$, such that $k = bT/2\sigma^2$, where b is the Boltzmann constant. (Note that this force constant k is one-half the magnitude of the force constant k' defined by Newton's law, $F = \mathrm{d}E/\mathrm{d}x = -k'x$.) This treatment resembles the generation of a mean field potential from the structure (*e.g.* Sippl, 1995), but is simplified for bond and angle parameters in several respects. Firstly, a single temperature is assumed; temperature dependence of equilibrium constants would require consideration of the temperatures of individual crystal structure determinations. Secondly, a normal-mode analysis would be required to eliminate redundancies arising from coupling between the parameters. Finally, the values of the variances are in many cases uncertain, due to poor statistical representation, non-Gaussian effects, or other causes (see below). Note that this simplified treatment of parameter uncertainty can be implemented more rigorously in maximum-entropy refinement methods (Pannu & Read, 1996; Bricogne, 1993).

18.3.2.2.1. Clustering

With ample computational power available for most refinement applications, the clustering of parameters into atom types might seem unnecessary. However, clustering is inevitable and occurs at least in the choice of fragments for deriving statistics. Values derived for individual residues, for example, effectively cluster three-dimensional structures together with a concomitant loss of information. For at least some residues with limited representation in the CSD, peptide geometries are best analysed as a general class, requiring clustering fragments into side-chain and main-chain classifications. Some side chains, such as arginine, also require smaller fragment definitions due to relatively small numbers in the CSD. The statistics listed here can be further clustered into fewer atom or bond-type classes. Inappropriate clustering, that is, the simultaneous analysis of fragments that are better represented by two or more fragment types with correspondingly various average values and sample variances, will exaggerate non-Gaussian distribution characteristics. In extreme cases, skew, kurtosis and especially multimodal distributions then provide evidence for a requirement to subdivide the fragment classes (see for example *cis*/*trans*-proline below). The effective clustering of the data presented here into largely conformation-

Table 18.3.2.1
Bond lengths of standard amino-acid side chains

EH denotes the values of Engh & Huber (1991), which were clustered according to atom type. The EH99 values are taken from recent Cambridge Structural Database releases with clustering of parameters only in the choice of fragments, based on amino acids. Parameters marked with an asterisk involving CA—CB bonds were taken from peptide fragment geometries. Two asterisks mark long-chain aliphatic parameters taken from arginine statistics. The number of fragments and the number of structures containing these fragments are noted after the amino-acid name. The fragments used for generating the statistics are described after the amino-acid name: incomplete valences indicate unspecified substituents with, however, specified orbital hybridization.

independent fragment definitions could be replaced by more specific information, especially as the database grows.

18.3.2.2.2. *Treatment of outliers*

A truly Gaussian distribution should include outliers at high σ values (about 0.01% for 4σ). We should expect, however, that the width of the distribution is affected not only by inherent variation in the variables to be parameterized, but also by variability in the experimental conditions (*e.g.* resolution) and by erroneous structures. This weakens a strategy of automatic rejection of outliers beyond a specific cutoff value. The possibility of visualizing the distributions with CSD software allows refinement of this rejection strategy, with, however, the introduction of considerable subjectivity in the criteria. For this work, a 4σ cutoff was generally considered a flag for erroneous outliers. However, broad and flat tails in the distribution were relatively frequent and often asymmetric. These deviations from Gaussian behaviour 'artificially' increased σ values. In these cases, the 4σ cutoff rule was not applied automatically, but was applied after examination and rejection of conspicuous outliers. From an algorithmic viewpoint, this was the additional use of skew and kurtosis (third and fourth moments of the distribution) for rejection criteria. In most cases, uncertainty in rejection criteria affected the average values little, but could significantly alter standard deviations.

18.3.2.3. *Bonds and angles*

18.3.2.3.1. *Peptide parameters: proline, glycine, alanine and CB substitution*

Fragments representing five-atom lengths of the backbone currently provide adequate statistics for peptide compositions of varieties including glycine, proline and side chains branched at CB. Peptide cyclicity was generally allowed on the assumption that this does not introduce distortions greater than typical protein secondary-structure interactions. The results are presented in Table 18.3.2.3. With one exception, none of the values deviates from those of 1991 by more than one sample standard deviation. However, the very large σ values for the proline C—N—CA and C—N—CD angles (Table 18.3.2.1) are conspicuous. Using high-resolution protein structures, Lamzin *et al.* (1995) identified geometries of proline that were inconsistent with high-resolution protein structures and also noted inconsistencies in C—CA—CB angle parameters (see also the sections on individual amino acids below). In the case of proline, a bimodal distribution of these parameters could be resolved with the discrimination between *cis* and *trans* forms (Fig. 18.3.2.1). A scatter plot of the angles against ω torsion angle resolves the averages (and σ's) of 122.6 (50) and 125.4 (44)° for C—N—CA and C—N—CD, respectively, into *cis*- and *trans*-dependent values with much smaller sample deviations (see Table 18.3.2.2). The large σ value for CB—CG remains, however, particularly for *trans*-proline. Its origin is unknown, but proline pucker may play a role.

Glycine, with its unique $\mathrm{CH_2}$ as CA, required new atom-type definitions for Engh & Huber (EH) (1991) parameterization to account for parameter-average differences of about one-half of a sample standard deviation. These also included C—N—CA, for which the average angles were 120.6° for glycine and 121.7° for the rest. The new statistics with 83 C—CO—NH—$\mathrm{CH_2}$—C fragments estimate a larger value of 122.3° for the glycine C—N—CA angle.

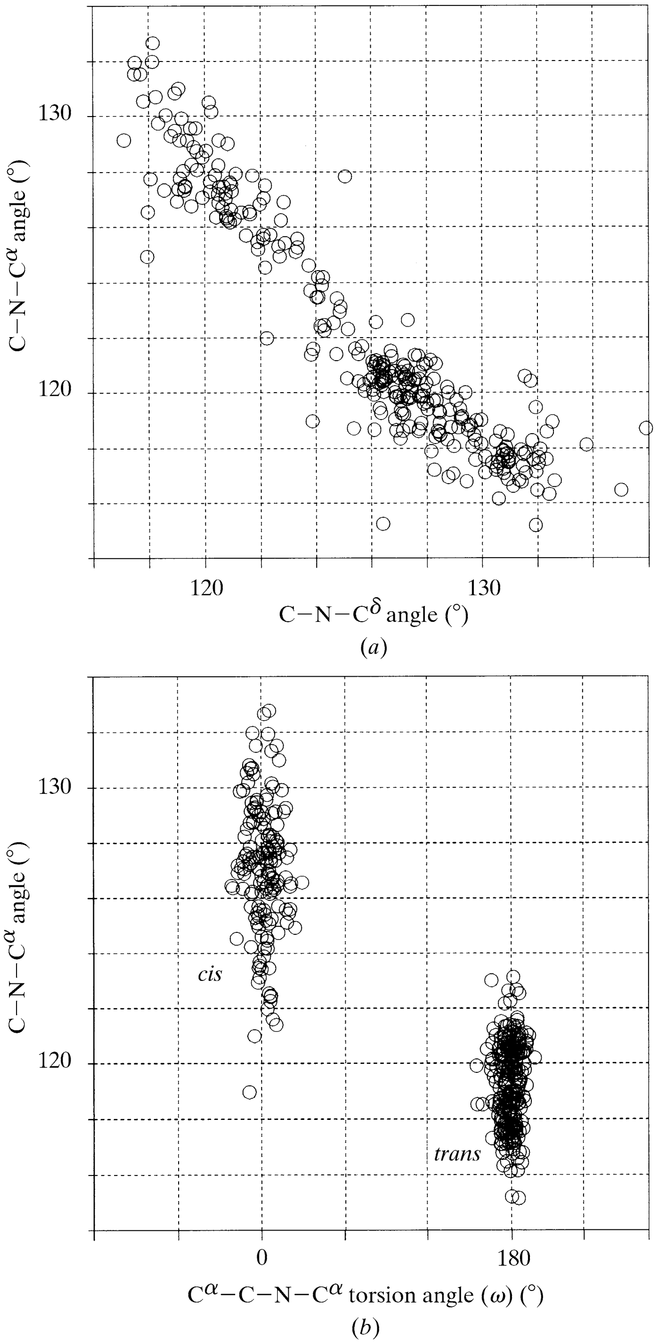

Figure 18.3.2.1
Torsion dependence of proline angle geometry. A one-dimensional frequency plot of either C—N—C$^{\alpha}$ or C—N—C$^{\delta}$ angles shows a broad and bimodal distribution. (*a*) A scatter plot of the two angles shows a very strong anticorrelation and suggests two minima. (*b*) Plotting either angle against the ω torsion angle resolves the broad distribution into two separate peaks.

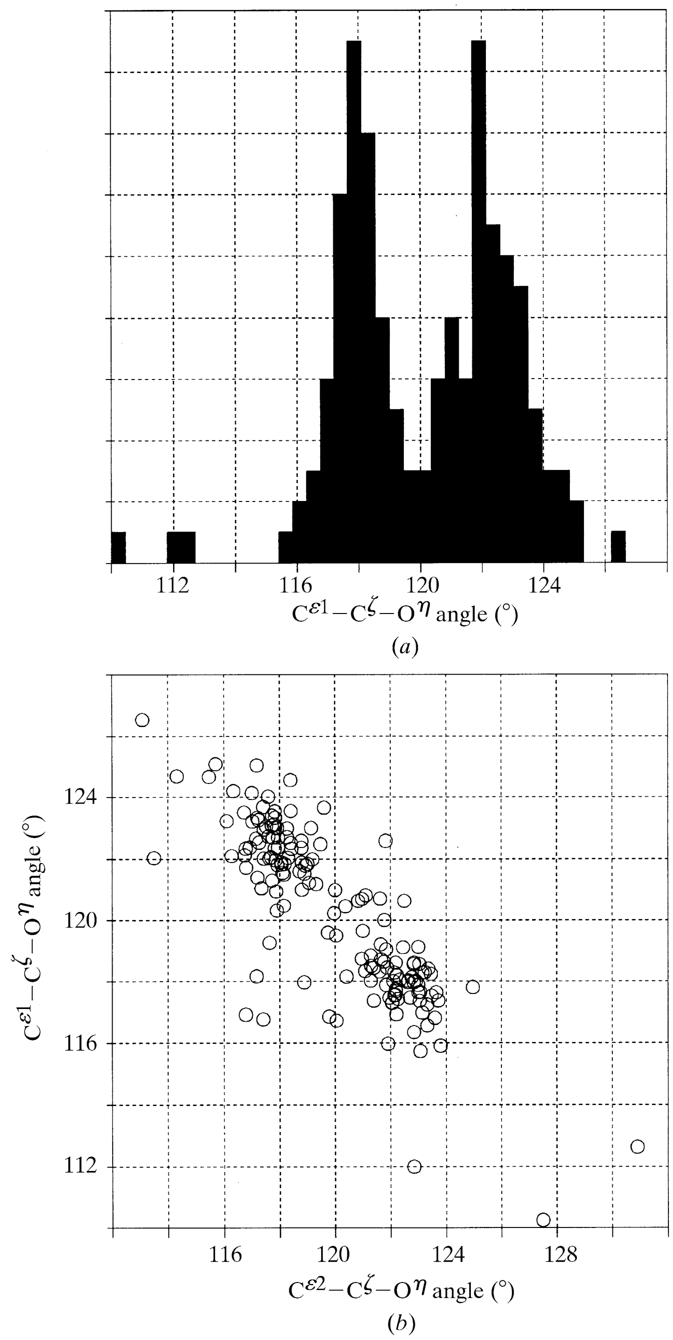

Figure 18.3.2.2
Bimodal distributions for tyrosine. (*a*) The C$^{\varepsilon}$—C$^{\zeta}$—O$^{\eta}$ angle distributions involving the tyrosine alcohol have maxima at 120 (2)°. (*b*) A scatter plot of the C$^{\varepsilon 2}$—C$^{\zeta}$—O$^{\eta}$ angle against the C$^{\varepsilon 1}$—C$^{\zeta}$—O$^{\eta}$ angle confirms that the C$^{\zeta}$—O$^{\eta}$ bond projects asymmetrically away from the aromatic ring.

'Extended atom'-type parameterizations, which cluster carbon atoms according to the number of bound hydrogen atoms, naturally separate parameters involving CB into values representing alanine and branched and unbranched side chains. Separate analyses of the bonds and angles for fragments depending on the number of hydrogen atoms at CB (1, 2 or 3) revealed significant variation for the C—CA—CB and N—CA—CB angles. The fragments chosen for peptide parameterization did not cover all possibilities for the peptide chain. In particular, effects of charges at the termini were not analysed. Also, specific residue sequences likely to have statistical effects, such as Pro-Pro (Bansal & Ananthanarayanan, 1988), were not analysed here. With 50–60 relevant fragments from the predominantly α-helical ROP protein, Vlassi *et al.* (1998) were able to compile statistics for main-chain bonds and angles and compare them with protein refinement parameters. Differences from EH were particularly significant for CO and CA—C bonds (1.237 and 1.508 Å, respectively) and for the O—C—N angle (121.35°). Excepting the proline O—C—N angle, for which the new CSD statistics predict an average value lowered to 121.1°, these values remained relatively unchanged. A likely source of the difference might be the predominantly helical structure of the ROP protein; the helical hydrogen bonding directly involves the C—O group in a systematic way.

† Alternate fragment definition including CA. † Bimodal distribution (see text).

18.3.2.3.2. Aromatic residues: tryptophan, phenylalanine, tyrosine, histidine

With the exception of generally lower σ values, tryptophan parameters remain essentially unchanged. Phenylalanine, also with generally lower σ values, is also essentially unchanged with the assumption of Gaussian distributions. However, a scatter plot of the CB—CG—CD1 *versus* CB—CG—CD2 angles shows an inverse correlation between these two angles, corresponding to ring rotations about an axis perpendicular to the ring face. Non-Gaussian distributions were most evident for tyrosine. In addition to the phenomenon described for phenylalanine, a clearly multimodal distribution was observed for the CE(1,2)—CZ—OH angles, with maxima at 118 and 122° (Fig. 18.3.2.2). The scatter plot of CE1—CZ—OH *versus* CE2—CZ—OH demonstrates that this distribution typifies individual fragments and does not arise from differing classes of fragments. This justifies an asymmetric parameterization for these angles; symmetric parameterization would require correspondingly soft force constants. The major difference between the histidine parameters listed here compared to those of EH arise from the appearance of HISD (uncharged; unprotonated at NE2) fragments in the CSD. The EH parameterization assumed values from other fragments. The total of 12 fragments is not large, but does predict some alterations in parameters involving the ring nitrogens. The fragment selection reported here did not investigate effects of noncovalent binding. For the aromatic residues, these include hydrogen-bonding effects (especially for histidine) and π-cloud interactions. Appropriate fragments exist in the database, so such dependencies are, in principle, accessible to investigation.

18.3.2.3.3. Aliphatic residues: leucine, isoleucine, valine

Compared to EH parameterization, the only notable features of the aliphatic residues were the leucine bonds and the C—CA—CB angles of isoleucine and valine. The leucine CD—CG(1,2) bonds retained relatively large σ values, which rather increased compared to the previous values. The C—CA—CB angle values, clustered as bare carbon/tetrahedral CH extended atom/tetrahedral CH_2 extended atom in EH, are sensitive to the degree of substitution at the CB carbon (Table 18.3.2.3, see the discussion of peptide fragments above). The statistics here show that the EH (1991) parameters were too small by about 2°.

18.3.2.3.4. Neutral polar residues: serine, threonine, glutamine, asparagine

These residues share neutral polarity, but are all geometrically distinct. Like leucine, valine and isoleucine described above, threonine is branched at CB, and the parameterization for C—CA—CB should be chosen accordingly. Additionally for threonine, the CA—CB—CG2 angle, clustered with valine as CH1E—CH1E—CH3E in EH (1991), should be altered from 110.5 to 112.4° according to the statistics reported here. The tabulated glutamine and asparagine parameters are taken from identical amide-group statistics, and parameters for the aliphatic atoms of glutamine are taken from arginine. This choice of fragments arose from a desire to maximize the number of fragments for the amide group; however, the individual residues might be expected to exhibit residue-specific amide structures.

18.3.2.3.5. Acidic residues: glutamate, aspartate

The fragment definitions were chosen to select both symmetrically and asymmetrically encoded carboxylate structures; that is, the statistics include carboxylate groups with delocalized charges as well as carboxylate groups encoded with a single charged oxygen atom. This distribution presumably reflects the variations in proteins as well. For both glutamic and aspartic acids, statistical variation in the asymmetry of delocalization was evident. One measure of parameter variation as a function of varying charge delocalization is the anticorrelation of C—O bond lengths and CH_2—C—O bond angles. For example, while the standard deviation of the corresponding aspartate bond lengths individually is 0.024 Å, the standard deviation of their pairwise average is 0.012 Å. Similarly, the standard deviation of the glutamate CH_2—C—O bond angles individually is 2.1° but the standard deviation of the pairwise average is 0.6°. This coupling of parameters is an example of additional information potentially available for structure refinement, but which would require new formulations of restraints.

18.3.2.3.6. Basic residues: arginine, lysine

The 98 arginine fragments in the database did not show alterations from the EH values, except generally tighter restraints at the guanidinium group. Lysine CD—CE bond lengths are somewhat shorter in the new statistics, while the two angles derived from the fragments remained similar.

18.3.2.3.7. Sulfur-containing residues: methionine, cysteine, disulfides

One of the most conspicuous features of the EH parameters is the soft force constant for the methionine SD—CE bond length. The 49 fragments now in the CSD also show a sample deviation for the 1.774 Å average bond length of 0.056 Å, and after one 4σ outlier rejection, the tabulated value of 1.779 Å still has a large sample deviation of 0.041 Å. In practice, the use of soft restraints during refinement often leads to warnings of relatively large deviations from the target value. Inspection of the CSD structures did not reveal an artificial source of this greater variability. Cysteines and disulfides here show reduced sample σ values for generally similar average target values.

18.3.2.4. Planarity restraints

Planarity and improper dihedral restraints, being ‘hard’ restraints, are amenable to the same kind of parameterization described above. Physically realistic deviations should be allowed. A survey of several planar atoms, such as CG of aromatic residues, the inter-ring carbons (CD2, CE2) of tryptophan and CZ of tyrosine, showed standard deviations about strict planarity of 1–2°. Statistically significant deviations of average values from perfect planarity might also be expected, particularly as a function of the protein fold environment. For example, an average nonzero planarity of the ω angle of the peptide bond has

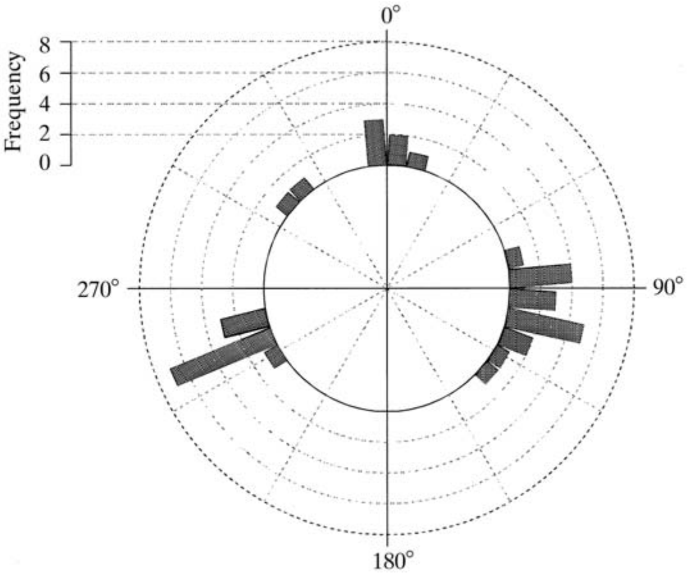

Figure 18.3.2.3

Tryptophan χ_2 dihedral angle distribution. The 36 tryptophan fragments in the CSD show several apparent minima, including an eclipsed $C^{\alpha}—C^{\beta}—C^{\gamma}—C^{\delta 1}$ dihedral conformation. This is apparent in χ_1, χ_2 tryptophan distribution plots from protein structures as well (Laskowski, MacArthur *et al.*, 1993).

Table 18.3.2.3
Bond lengths (Å) and angles (°) of peptide backbone fragments

EH denotes parameters from Engh & Huber (1991). Bold values mark important updates for angles involving proline (with *cis* and *trans* distinction) and branched CB atoms (isoleucine, valine, threonine). The number of fragments used for the statistics is given. The standard deviation of each value is given in parentheses following the value and is on the scale of the least significant digit of the value.

been noted (Marquart *et al.*, 1983) and attributed at least in part to secondary structure; such effects may be misrepresented in statistics from small molecules.

18.3.2.5. *Torsion angles*

Since torsion angles are generally more adequately determined by protein structures of typical resolutions, there is less need to derive parameters from the CSD for refinement purposes. Further, distributions derived from small molecules may not be representative of torsion angles among proteins, since typical fragments lack 'typical' protein secondary structure. This kind of environmental dependence will affect softer parameters such as dihedral angles more than bonds or angles. However, since the torsion-angle distribution is a function not only of potential interactions of the peripheral groups but of the electronic character of the bond itself, some questions may be best examined by the study of chemical fragments. One such feature might be the $\chi_1\chi_2$ distributions for aromatic residues. Statistical distributions of side-chain orientations show the apparent stability of an eclipsed χ_2 conformation, particularly for $\chi_1 = 300°$ (g^- conformer, Fig. 18.3.2.3). If the relative dearth of secondary structure leads to atypical torsion-angle distributions in proteins, it must be conversely expected that torsion-angle statistics derived from the set of all proteins will be less applicable, for example, to helical proteins than statistics derived from mostly helical proteins. This illustrates the dilemma of selecting the ideal statistical database for protein refinement.

18.3.2.6. *Non-bonded interactions*

Like the potential parameterization of torsion-angle statistics with the CSD, parameterization of non-bonded interactions, typically into terms representing packing (an empirical mix of London dispersion forces and solvent effects), electrostatics and hydrogen bonding, is probably more strongly influenced by protein environment than are bond and angle terms. Specific chemical questions are likely to be best addressed with fragment structure databases, however, for improved parameterization or structure-quality evaluation. Possible examples include hydrogen bonds, salt bridges (see, *e.g.*, the discussion on charge delocalization of Glu and Asp above) *etc.* These are particularly relevant for structures generally atypical among proteins, such as at enzyme reactive sites.

18.3.2.7. *Effects of hydrogen atoms in parameterization*

While many CSD fragments include hydrogen-atom positions, their accuracy is necessarily the most limited. Evaluation of CSD statistics without hydrogens and the subsequent addition of parameters to refine hydrogens adds an additional artifactual coupling between parameters involving non-hydrogen atoms as well. This artifactual coupling might theoretically be of some concern, but is a second-order effect and presumably introduces effects smaller than the artifactual coupling between non-hydrogen parameters, for example.

18.3.2.8. *Special geometries: cofactors, ligands, metals etc.*

Most crystallographers will experience neither the need nor desire to derive their own parameterization for general protein structure refinement; many, however, need new parameters for ligands or other entities that are not amino-acid residues. The accuracy required for their application will determine the appropriate effort. If the purpose of the structure is to determine the general orientation of an inhibitor for molecular modelling studies with a still lower effective accuracy, it may be that no refinement (and no parameterization) is necessary at all. As the accuracy requirements increase, so does the need for good parameterization and a way of estimating when the density is incompatible with known structures. Such incompatibility may be decisive in identifying the stereochemistry of ligands selected from racemic mixtures, or the occurrence of a chemical reaction, or even falsely characterized substances. For such applications, small-molecule structural databases will remain the only choice for parameter derivation, which can be done exactly as for amino-acid fragments.

18.3.2.9. Addition of tailored information sources

When specific structural effects are observed which are not otherwise parameterized, new parameters might be desirable to encode this information. In the case of new statistical minima or variances of parameters already encoded by the refinement program, it is for most programs a simple matter to introduce new atom types, residues, or fragment names to the topology and parameter libraries. Examples include new parameterization for charged states or for *cis*- and *trans*-proline. If the reason for the new statistics is structural, the structure must be appropriately monitored during refinement to ensure that the conditions continue to hold, particularly in the case of simulated-annealing refinement steps.

18.3.3. Strategy of application during building/refinement

Refinement parameters necessarily and intentionally introduce bias into the refinement which may not disappear with later alterations of parameters. The importance of this fact is reflected by the observation that the parameters of refined structures can be recognized by statistical studies of the structures (Laskowski, Moss & Thornton, 1993). It is therefore important that the parameters initially reflect what can be confidently predicted about the structure. If unknown geometries may be expected, at metal or catalytic sites, for example, or if isomerization states need to be recognized from the refined structure, all relevant parameters must be initially eliminated from the refinement. Depending on the resolution of the structure and the detail required, the unbiased final refined structure may sufficiently demonstrate the unknown structural quantities. On the other hand, insufficient restraint may allow unreasonable geometries that do not allow recognition of the desired quantity. In this case, it may be necessary to test all possible restraint conditions and compare the results of the refinements.

18.3.3.1. Confidence in restraints versus information from diffraction

Primarily in cases of new structures, such as small-ligand- or metal-binding proteins, the refinement may indicate that the expected geometries and applied restraints seem incompatible with evidence from the electron density. Several sources for such discrepancies must be considered for an evaluation of the true geometries or the confidence level of such an evaluation. The quality of the experimental information, such as data resolution and reduction parameters, must be considered. Physical phenomena possibly ignored by the refinement model might include anisotropies of motion and/or electron distribution, or disorder in the crystal. These might lead to systematic deviations in the refined structure that mimic alternate parameterizations. Finally, newly derived parameters should be examined to decide whether the fragments and chemical environments were inappropriate for the refinement problem, or whether errors in fragment structures artifactually distorted the parameterization.

18.3.4. Future perspectives

It seems obvious to seek the best (most accurate) possible parameterization and establish it as a standard (to enable statistical structure comparisons). This does not seem to be a realistic goal for several reasons. Firstly, the parameterization is less a determinant of accuracy than the quality of the data and the method of refinement. Secondly, the quality of existing parameterization and the potential for new environment-dependent parameters improves as more structures are solved and databases grow. Such new parameters can be derived from conformation-dependent statistics (*cis*- and *trans*-proline is an example described above), hydrogen-bonding geometries *etc.* Finally, protein structures are generally solved not to build a statistically optimized protein database, but to discover biophysical functional mechanisms.

The growth of structural databases will improve our understanding of structural properties (Wilson *et al.*, 1998); the highest-resolution protein structures will contribute most to the database, while low-resolution structures will profit most from improved predictive power. Structures that require restrained refinement both draw on the database for refinement parameters and integrity checks, and also contribute to it; a kind of bootstrapping procedure to re-refine deposited structures with iteratively improved parameters is conceivable (if convergent). The consequent removal of parameterization 'signatures' in, *e.g.*, bond and angle parameters seems unlikely to have practical consequences beyond identification of, *e.g.*, catalytically relevant outliers, but qualitative improvements in structure comparison might be revealing in unexpected ways. Such an effort will require adequate computational resources and the deposition of structure factors or, even better, diffraction images.

Chapter 18.4. Refinement at atomic resolution

Z. Dauter, G. N. Murshudov and K. S. Wilson

18.4.1. The atomic model and a definition of atomic resolution

18.4.1.1. The atomic model

X-rays are diffracted by the electrons that are distributed around the atomic nuclei, and the result of an X-ray crystallographic study is the derived three-dimensional electron-density distribution in the unit cell of the crystal. The elegant simplicity and power of X-ray crystallography arise from the fact that molecular structures are composed of discrete atoms that are treated as spherically symmetric in the usual approximation. This property places such strong restraints on the Fourier transform of the crystal structures of small molecules that the phase problem can be solved by knowledge of the amplitudes alone.

Each atom or ion can be described by up to 11 parameters (Table 18.4.1.1).

The first parameter is the scattering-factor amplitude for the chemical nature of the atom in question, and has been computed and tabulated for all atom types [*International Tables for Crystallography*, Volume C (2004)]. Once the chemical identity of the atom is established, this parameter is fixed.

The next three parameters relate to the positional coordinates of the atom with respect to the origin of the unit cell.

If the resolution is high enough, then the number of observed reflections is sufficient to allow six anisotropic atomic displacement parameters to be used to describe the distribution of the atom positions in different unit cells (Fig. 18.4.1.1). Atomic displacement parameters (ADPs) reflect both the thermal vibration of atoms about the mean position as a function of time (dynamic disorder) and the variation of positions between different unit cells of the crystal arising from its imperfection (static disorder). Contributors to the apparent ADP ($U_{\rm atom}$) can be thought of as follows (Murshudov *et al.*, 1999):

$$U_{\rm atom} = U_{\rm crystal} + U_{\rm TLS} + U_{\rm torsion} + U_{\rm bond}, \qquad (18.4.1.1)$$

where $U_{\rm crystal}$ represents the fact that a crystal itself is in general an anisotropic field that will result in the intensity falling off in an anisotropic manner, $U_{\rm TLS}$ represents a translation/libration/screw (TLS), *i.e.* the overall motion of molecules or domains (Schomaker & Trueblood, 1968; Winn *et al.*, 2001), $U_{\rm torsion}$ is the oscillation along torsion angles and $U_{\rm bond}$ is the oscillation along and across bonds. In principle, all these contributors are highly correlated and it is difficult to separate them from one another. Nevertheless, an understanding of how $U_{\rm atom}$ is a sum of these different components makes it possible to apply atomic anisotropy parameters at different resolutions in a different manner. For example, $U_{\rm crystal} + U_{\rm TLS}$ can be applied at any resolution, as their refinement increases the number of parameters by at most five for $U_{\rm crystal}$ and 20 per independent moiety for $U_{\rm TLS}$. In contrast, refinement of the third contributor does pose a problem, as there is strong correlation between different torsion angles. As an alternative, ADPs along the internal degrees of freedom could in principle be refined. The fourth and final contributor, $U_{\rm bond}$, can only be refined at very high resolution. In real applications, $U_{\rm crystal}$ and $U_{\rm TLS}$ are separated for convenient description of the system, but in practice their effects are indistinguishable.

In the special case when the tensor $U_{\rm atom}$ is isotropic, *i.e.*, all non-diagonal elements are equal to zero and all diagonal terms are equal to each other, then the atom itself appears to be isotropic and its ADP can be described using only one parameter, $U_{\rm iso}$.

Thus, for a full description of a crystal structure in which all atoms only occupy a single site, nine parameters per atom must be determined: three positional parameters and six anisotropic ADPs. This assumes that the spherical-atom approximation applies and ignores the so-called deformation density resulting from the non-spherical nature of the outer atomic and molecular orbitals involved in the chemical interactions between the atoms (Coppens, 1997).

For disordered regions or features, where atoms can be distributed over two or more identifiable sites, the occupancy introduces a tenth variable for each atom. In many cases, the fractional occupancies are not all independent, but are rather constant for sets of covalently or hydrogen-bonded atoms or for those in non-overlapping solvent networks. This would apply, for example, to partially occupied ligands or side chains with two conformations.

Table 18.4.1.1
The parameters of an atomic model

Parameter type	Number	Variable or fixed
Atom type	1	Fixed after identification
Positional (x, y, z)	3	Variable, subject to restraints
ADPs:		
isotropic	1	Variable beyond about 2.5 Å
anisotropic	6	Variable beyond about 1.5 Å
Occupancy	1	Variable for visible disorder

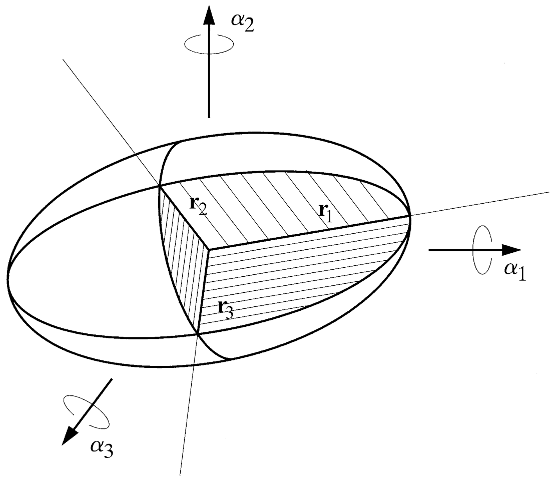

Figure 18.4.1.1
The thermal-ellipsoid model used to represent anisotropic atomic displacement, with major axes indicated. The ellipsoid is drawn with a specified probability of finding an atom inside its contour. Six parameters are necessary to describe the ellipsoid: three represent the dimensions of the major axes and three the orientation of these axes. These six parameters are expressed in terms of a symmetric U tensor and contribute to atomic scattering through the term $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{12}hka^*b^*\cos\gamma^* + 2U_{13}hla^*c^*\cos\beta^* + 2U_{23}klb^*c^*\cos\alpha^*)]$.

18.4.1.2. *What is 'atomic resolution'?*

Atomicity is the great simplifying feature of crystallography in terms of structure solution and refinement. For a small-molecule structure, accurate X-ray data usually extend to 0.8 Å, and this has three important implications for crystallography.

(1) *Ab initio phasing using direct methods*. Automatic *ab initio* solution of the phase problem depends on the assumption of positivity and atomicity of the electron density. The fact that current *ab initio* methods in the absence of heavy atoms are only effective when meaningful data extend beyond 1.2 Å reinforces the idea that this is a reasonable working criterion for its definition as atomic resolution. In addition, approaches such as solvent flattening and automated map interpretation benefit enormously from such data.

(2) *Resolved atomic peaks in the Fourier maps*. Although some individual peaks can be seen at resolutions beyond ~2.0 Å, they become more fully resolved at around 1.2 Å.

(3) *Refinement of a full anisotropic model*. The number of reflections is sufficient for the minimization of the discrepancy between the experimentally determined amplitudes or intensities of the Bragg reflections and those calculated from the atomic model with up to ten (usually nine) independent parameters per atom. This has been classically achieved by least-squares refinement as described in *International Tables for Crystallography* Volume C, Chapter 8.1 (Prince & Boggs, 2004) or more recently by maximum-likelihood procedures (Bricogne & Irwin, 1996; Pannu & Read, 1996; Murshudov *et al.*, 1997). For small-molecule structures, accurate amplitude data are normally available to around 0.8 Å, giving an observation-to-parameter ratio of about seven for noncentrosymmetric crystals, which allows positional parameters to be determined with an accuracy approaching 0.001 Å. This reflects the high degree of order of such crystals, in which the molecules in the lattice are in a close-packed array. In addition the X-ray data are of high quality, with a high $I/\sigma(I)$ ratio (and hence low merging R value) even in the outer resolution shells.

It is now necessary to define what constitutes 'atomic resolution'. A pragmatic approach has been that data extending to 1.2 Å or better with at least 50% of the intensities in the outer shell being higher than 2σ is the acceptable limit (Sheldrick, 1990; Sheldrick & Schneider, 1997), which means that the statistical problem of refinement is overdetermined. This appears to remain a good working definition for refinement applications and indeed has been put on a more solid theoretical basis (Morris & Bricogne, 2003; Morris *et al.*, 2004). However, for application of direct phasing methods it is advantageous to record even a small fraction of significant reflections beyond this cutoff. These outer shells should be included in the refinement procedure with correct maximum-likelihood weights, but they will not significantly improve the effective resolution.

This is rarely achieved for crystals of macromolecules: as of October 2009 around 1250 out of 52 000 crystal structures in the Protein Data Bank (PDB) had a resolution higher than 1.2 Å compared to 157 out of 13 000 in March 2000. Firstly, the large unit-cell volume leads to an enormous number of reflections for which the average intensity is weak compared to those for small molecules (see Table 9.1.1.1 in Chapter 9.1). Secondly, the intrinsic disorder of the crystals further reduces the intensities at high Bragg angles and usually gives a resolution cutoff which is much less than atomic. Thirdly, the large solvent content leads to substantial decay of crystal quality under exposure to the X-ray beam at room temperature. While the secondary damage (resulting from the migration of ions and radicals produced by the primary absorption event) is largely avoided by vitrification of such crystals, the effect of primary damage has become significant on high intensity beamlines (see Section 9.1.12). The upper resolution limit of the data affects all stages of a crystallographic analysis, but especially restricts the features of the model that can be independently refined (Table 18.4.1.2). Solutions to the problem of refining macromolecular structures with a paucity of experimental data evolved during the 1970s and 1980s with the use of either constraints or restraints on the stereochemistry, based on that of known small molecules. With constraints, the structure is simplified as a set of rigid chemical units (Diamond, 1971; Herzberg & Sussman, 1983), whereas using restraints, the observation-to-parameter ratio is increased by introduction of prior chemical knowledge of bond lengths and angles (Konnert & Hendrickson, 1980).

Table 18.4.1.2
Features which can be seen in the electron density at different resolutions

Disordered regions will not necessarily be visible even at these limiting values. Some features should be included even at lower resolutions, *e.g.* hydrogen atoms at their riding positions can be incorporated at 2.0 Å, but their positions will not be verifiable from the density. The contents of this table should not be taken as dogmatic rules, but as approximate guidelines.

Resolution (Å)	Feature
0.8	Deformation density, *i.e.* deviation from the spherical-atom model
1.0	Hydrogen atoms
1.5	Anisotropic atomic displacement
2.0	Multiple conformations
2.5	Individual isotropic atomic displacement
3.5	Overall temperature factor
4.0	α-Helices and β-sheets
6.0	Domain envelopes

As expected, atoms with different ADPs contribute differently to the diffraction intensities, as discussed by Cruickshank (1999*a*,*b*). The relative contribution of the different atoms to a given reflection depends on the difference between their ADPs $\{\exp[-(B_1 - B_2)s^2]$, where $s = \sin\theta/\lambda\}$. Clearly, if the average ADP of a molecule is small, then the spread will also be narrow, and most atoms will contribute to diffraction over the whole range of resolution. When the mean ADP is large, then the spread of the ADPs will be wide, and fewer atoms will contribute to the high-resolution intensities (Fig. 18.4.1.2).

Three advances in experimental techniques have combined effectively to overcome these problems for an increasing number of well ordered macromolecular crystals, namely the use of high-intensity synchrotron radiation (SR), efficient two-dimensional detectors and cryogenic freezing (discussed in Parts 8, 7 and 10, respectively). These advances mean that there is no longer a sharp division between small-molecule and macromolecular crystallography, but rather a continuum from small through medium-sized structures, such as cyclodextrins and other supramolecules, to proteins. The inherent disorder in the crystal generally increases with the size of the structure, due in part to the increasing solvent content. Thus, it has become tractable to refine a significant number of protein structures at atomic resolution with a full anisotropic model (Dauter, Lamzin & Wilson, 1997; Dauter, 2003). This work of course benefits tremendously from the experience and algorithms of small-molecule crystallography, but does pose special problems of its own. The tech-

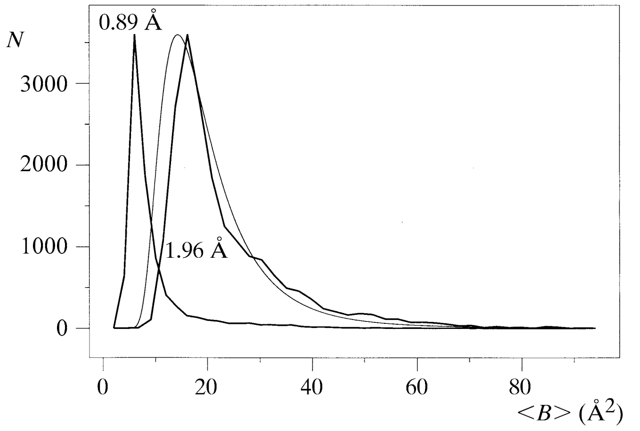

Figure 18.4.1.2
Histograms of B values for a protein structure, *Micrococcus lysodecticus* catalase (Murshudov *et al.*, 1999), for two different crystals which diffracted to different limiting resolutions. For both crystals, the resolution cutoff reflects the real diffraction limit from the sample, and hence its level of order. At 0.89 Å, the mean B value is 8.3 Å^2 and the width of the distribution is small. In contrast, at 1.96 Å, the mean B value is 25.5 Å^2 and the spread is correspondingly large. Thus, for the 0.89 Å crystal, most atoms contribute to the high-resolution terms, whereas for the 1.96 Å crystal, only the atoms with lower B values do so. The thin line shows the theoretical inverse gamma distribution $\mathrm{IG}(B) = (b/2)^{d/2}/\Gamma(d/2)B^{-(d+2)/2}\exp[-b(2B)]$, where b and d are the parameters of the distribution, and Γ is the gamma function. For this figure, the values $b = 2$ and $d = 10$ were chosen, which correspond to a mean B value of 20 Å^2 and σ_B of 11 Å^2. In the gamma distribution, the abscissa was multiplied by $8\pi^2$ to make it comparable with the measured B values. All three histograms were normalized to the same scale.

niques of solving and refining macromolecular structures thus also overlap with those conventionally used for small molecules; a prime example is the use of *SHELXL* (Sheldrick, 2008), which was developed for small structures and has now been extended to treat macromolecules.

18.4.1.3. A theoretical approach to 'atomic resolution'

An alternative and stricter definition of atomic resolution comes from using a measure of the information content of the data. There are a variety of definitions of the information in the data about the postulated model (see, for example, O'Hagan, 1994). A suitable one is the Bayesian definition for quadratic information measure:

$$I_Q(p, F) = \operatorname{tr}(A\{\operatorname{var}(p) - E[\operatorname{var}(p, F)]\}), \qquad (18.4.1.2)$$

where I_Q is the quadratic information measure, p is the vector of parameters, F is the experimental data, var(p) is the variance matrix corresponding to prior knowledge, var(p, F) is the variance matrix corresponding to the posterior distribution (which includes prior knowledge and likelihood), E is the expectation, tr is the trace operator (*i.e.* the sum of the diagonal terms of the matrix) and A is the matrix through which the relative importance of different parameters or combinations of parameters is introduced. For example, if A is the identity matrix, then the information measure is unitary and all parameters are assigned the same weight. If A is the identity matrix for positional parameters and zero for ADPs, then only the information about positional parameters is included. By appropriate choice of A, the information about selected key features, such as the active site, can be estimated.

Equation (18.4.1.2) shows how much the experiment reduces the uncertainty in given parameters. Prior knowledge is usually taken to be information about bond lengths, bond angles and other chemical features of the molecule, known before the experiment has been carried out. In the case of an experiment designed to provide information about the ligated protein or mutant, when information about differences between two (or more) different states is needed, the prior knowledge can be thought of in a different way – as knowledge about the native protein.

Unfortunately, there are problems in applying equation (18.4.1.2). Firstly, careful analysis of the prior knowledge and its variance is essential. The target values used at present, or more properly the distributions for these values, need to be re-evaluated. Another problem concerns the integration required to compute the expectation value (E). Nevertheless, the equation provides some idea of how much information about a postulated model can be extracted from a given experiment.

This alternative definition of atomic resolution assumes that the second term of equation (18.4.1.2) for positional parameters is sufficiently close to zero for most atoms to be resolved from all their neighbours. Defining atomic resolution using this information measure reflects the importance of both the quality and quantity of the data [through the posterior var(p, F)]. In addition, data may come from more than one crystal, in which case the information will be correspondingly increased. There may be additional data from mutant and/or complexed protein crystals, where, again, the information measure will be increased and, moreover, the differences between different states can be analysed. The effect of redundancy of different crystals of the same molecule(s) in different space groups is to reduce the limit of data necessary for achieving atomic resolution, which is equivalent to the advantage of noncrystallographic averaging.

Thus, in practice, while it would be ideal to develop the strict application of equation (18.4.1.2), for the present it is necessary to rely on the pragmatic approach in Section 18.4.1.2.

18.4.2. Data

The quality of the refined model relies finally on that of the available experimental data. Data collection has been covered extensively in Chapter 9.1 and will not be discussed here.

18.4.2.1. Data quality

As can be seen from equation (18.4.1.2), the measure of information about all or part of the crystal contents depends strongly on the quality and quantity of the data. Of course, before the experiment is carried out some questions should be answered. Firstly, what is the aim of the experiment? Secondly, what is the cost of the experiment and what are the available resources? With modern techniques, if SR is used with an efficient detector, the cost of the experiment for different resolutions does not vary greatly (provided that a suitable quality crystal is available). In practice, the apparent increase in cost to attain high-resolution data will generally make solving the phase problem both easier and faster. A full analysis at atomic resolution provides a wealth of additional structural detail which may shed light on the subtleties of the protein's chemistry not seen at lower resolution. However, this may require some considerable time and effort, and is an area where development of more automated approaches would be beneficial. In contrast, low-resolution data can make it difficult to answer not only the question currently being asked, but can also necessitate further experiments to address other problems that arise.

While the information content of the data appears to depend quantitatively on the nominal resolution, in fact it is dependent on the data quality throughout the resolution range, and both high- and low-resolution completeness and their statistical significance affect the information content of the data and derived model. High-intensity low-resolution terms remain important for refinement at atomic resolution, as they define the contrast in the density maps between solvent and protein, and because their omission biases the refinement, especially that of parameters such as the ADPs. To judge the effective resolution of the diffraction data set, the concept of 'optical resolution', which can be estimated from the shape of the origin peak in the Patterson synthesis, may be very useful (Vaguine *et al.*, 1999).

The rejection of low-intensity observations will also introduce bias. In particular, all the maps calculated for visual or computer inspection by Fourier transformation are diminished in quality by omission of any terms, but are especially affected by omission of strong low-resolution data. This is particularly true in the early stages of structure solution, where low-resolution data can be vital. Although most phase-improvement algorithms rely on relations between all reflections, terms involving low-resolution reflections will be large, will be involved in many relations and will play a dominant role. Hence, omission of these terms will severely degrade the power of these methods, which may indeed converge to solutions that have nothing whatsoever to do with the real structure.

18.4.2.2. Anisotropic scaling

The intensity data from a crystal may display anisotropy, *i.e.*, the intensity fall-off with resolution will vary with direction, and may be much higher along one crystal axis than along another. If the structure is to be refined with an isotropic atomic model (either because there are insufficient data or the programs used cannot handle anisotropic parameters), then the fall-off of the calculated F^2 values will, of necessity, also be isotropic. In this situation, an improved agreement between observed and calculated F^2 values can be obtained either by using anisotropic scaling during data reduction to the expected Wilson distribution of intensities, or by including a maximum of six overall anisotropic parameters during refinement. This will result in an isotropic set of F^2 values. For crystals with a high degree of anisotropy in the experimental data, this can lead to a substantial drop of several per cent in R and $R_{\rm free}$ (Sheriff & Hendrickson, 1987; Murshudov *et al.*, 1998).

This ambiguity effectively disappears with use of an anisotropic atomic model. The individual ADPs, including contributions from both static and thermal disorder, take up relative individual displacements, but also the overall anisotropy of the experimental F^2 values. The significance of the overall anisotropy is a point of some contention, and its physical meaning is not clear. It may represent asymmetric crystal imperfection or anisotropic overall displacement of molecules in the lattice related to TLS parameters. Refinement of TLS parameters, which can be performed using, for example, *RESTRAIN* (Driessen *et al.*, 1989) *REFMAC* (Winn *et al.*, 2001) or *PHENIX.REFINE* (Terwilliger *et al.*, 2008), removes the overall crystal contribution to the ADPs.

It is important that at least the intensity or amplitude data be deposited in the PDB as measured, without any anisotropic correction being applied. For the refined model, complete information on any overall anisotropic and TLS modelling must be explicitly included, as well as the individual atomic ADPs.

18.4.3. Computational algorithms and strategies

18.4.3.1. Classical least-squares refinement of small molecules

The principles of the least-squares method of minimization are described in *International Tables for Crystallography* Volume C (2004). Least squares involves the construction of an order $N \times N$ normal matrix, where N is the number of parameters, representing a system of least-squares equations, whose solution provides estimates of adjustments to the current atomic parameters. The problem is nonlinear and the matrix construction and solution must be iterated until convergence is achieved. In addition, inversion of the matrix at convergence provides an approximation to the standard uncertainties for each individual parameter refined according to the Cramer–Rao inequality (Stuart *et al.*, 1999). Indeed, this is the only method available so far that gives such estimates properly.

However, even for small molecules there may be some disordered regions which will require the imposition of restraints, as is the case for macromolecules (see below), and the presence of such restraints means that the error estimates no longer reflect the information from the X-ray data alone. If the problem of how restraints affect the error estimates could be resolved, then inversion of the matrix corresponding to the second derivative of the posterior distribution would provide standard uncertainties incorporating both the prior knowledge, such as the restraints, and the experimental data. Equation (18.4.1.2) for information measure could then be applied, but this requires further development. For small structures, the speed and memory of modern computers have reduced the requirements for such calculations to the level of seconds, and the computational requirements form a trivial part of the structure analysis. Recent developments in the application of fast Fourier transform methods to normal matrix–vector multiplication (Strokopytov, 2008) and fast information matrix evaluation (Steiner *et al.*, 2003) suggest that fast calculations for macromolecular structures may be available in the foreseeable future.

18.4.3.2. Least-squares refinement of large structures

The size of the computational problem increases dramatically with the size of the unit cell, as the number of terms in the matrix increases with the square of the number of parameters. Furthermore, construction of each element depends on the number of reflections. For macromolecular structures, computation of a full matrix is at present prohibitively expensive in terms of CPU time and memory. A variety of simplifying approaches have been developed, but all suffer from a poorer estimate of the standard uncertainties and from a more limited range and speed of convergence.

The first is the block-matrix approach, where instead of the full matrix, only square blocks along the matrix diagonal are constructed, involving groups of parameters that are expected to be correlated. The correlation between parameters belonging to different blocks is therefore neglected completely. In this way, the whole least-squares minimization is split into a set of smaller independent units. In principle this leads to the same solution, but more slowly and with less precise error estimates. Nevertheless, block-matrix approaches remain essential for tractable matrix inversion for macromolecular structures.

A further simplification involves the conjugate-gradient method or the diagonal approximation to the normal matrix (the second derivative of minus the log of the likelihood function in the case of maximum likelihood), which essentially ignores all off-diagonal terms of the least-squares matrix. For the conjugate-gradient approach, all diagonal terms of the matrix are equal. However, the range and speed of convergence are substantially reduced, and standard uncertainties can no longer be estimated directly by matrix inversion.

18.4.3.3. Fast Fourier transform

Conventional least-squares programs use the structure-factor equation and associated derivatives, with the summation extending over all atoms and all reflections. This is immensely slow in computational terms for large structures, but it has the advantage of providing precise values.

An alternative procedure, where the computer time is reduced from being proportional to N^2 to $N \log N$, involves the use of fast Fourier algorithms for the computation of structure factors and derivatives (Ten Eyck, 1973, 1977; Agarwal, 1978). This can involve some interpolation and the limitation of the volume of electron-density maps to which individual atoms contribute. Such algorithms have been exploited extensively in macromolecular refinement programs such as *PROLSQ* (Konnert & Hendrickson, 1980), *XPLOR* (Brünger, 1992*b*), *TNT* (Tronrud, 1997), *RESTRAIN* (Driessen *et al.*, 1989), *REFMAC* (Murshudov *et al.*, 1997), *CNS* (Brünger *et al.*, 1998) and *PHENIX.REFINE* (Terwilliger *et al.*, 2008), but have largely been restricted to the diagonal approximation. *XPLOR* and *CNS* use the conjugate-gradient method, which relies only on the first derivatives and ignores the second derivatives. In all other programs, the diagonal approximation is used for the second-derivative matrix.

18.4.3.4. Maximum likelihood

This provides a statistically sounder alternative to least squares, especially in the early stages of refinement when the model lies far from the minimum. This approach increases the radius of convergence, takes into account experimental uncertainties, and in the final stages gives results similar to least squares but with improved weights (Bricogne & Irwin, 1996; Murshudov *et al.*, 1997). The maximum-likelihood approach has been extended to allow refinement of a full atomic anisotropic model while retaining the use of fast Fourier algorithms (Murshudov *et al.*, 1999). A remaining limitation is the use of the diagonal approximation, which prevents the computation of standard uncertainties of individual parameters. Algorithms that will alleviate this limitation can be foreseen, and they are expected to be implemented in the future.

18.4.3.5. Twinning

A non-negligible fraction of protein crystals turn out to be merohedrally twinned (Lebedev *et al.*, 2006), which requires special treatment of the diffraction data and proper treatment of this phenomenon during structure solution and more especially refinement (Yeates, 1997; Chapters 18.11 and 18.12). The twinning problem can be approached in two distinctly different ways. In the first, the data are explicitly 'detwinned' to produce an adjusted set of amplitudes [for example using the UCLA detwinning server (http://nihserver.mbi.ucla.edu/Twinning/) or the *DETWIN* program (Collaborative Computational Project, Number 4, 1994)], which are then subjected to conventional refinement. However, detwinning can only be successfully applied if the twinning fraction is not too high, since the error in the resulting amplitudes increases as the fraction approaches 50%. A second, and certainly preferred, approach is to include the twinning fraction as a variable during refinement. This has been implemented in *SHELXL*, *PHENIX.REFINE* and *REFMAC*, and is widely used. In *CNS*, it is possible to set the twin fraction, but not to refine it. This is of special relevance for atomic resolution structures, as even a small degree of twinning will have a significant effect on the interpretability of fine features.

18.4.3.6. Computer power

There are no longer any restrictions on the full-matrix refinement of small-molecule crystal structures. However, the large size of the matrix, which increases as N^2, where N is the number of parameters, means that for macromolecules with thousands of independent atoms this approach is intractable with the computing resources normally available to the crystallographer. By extrapolating the progress in computing power experienced in recent years, it can be envisaged that the limitations will disappear during the next decade, as those for small structures have disappeared since the 1960s. Indeed, the advances in the speed of CPUs, computer memory and disk capacity continue to transform the field.

18.4.4. Computational options and tactics

18.4.4.1. Use of F (amplitudes) or F^2 (intensities)

The X-ray experiment provides two-dimensional diffraction images. These are transformed to integrated but unscaled data, which are transformed to Bragg reflection intensities that are subsequently transformed to structure-factor amplitudes. At each transformation some assumptions are used, and the results will depend on their validity. Invalid assumptions will introduce bias toward these assumptions into the resulting data. Ideally, refinement (or estimation of parameters) should be against data that are as close as possible to the experimental observations, eliminating at least some of the invalid assumptions. Extrapolating this to the extreme, refinement should use the images as observable data, but this poses several severe problems, depending on data quantity and the lack of an appropriate statistical model.

Alternatively, the transformation of data could be improved by revising the assumptions. The intensities are closer to the real experiment than are the structure-factor amplitudes, and use of intensities would reduce the bias. However, there are some difficulties in the implementation of intensity-based likelihood refinement (Pannu & Read, 1996).

Gaussian approximation to intensity-based likelihood (Murshudov *et al.*, 1997) would avoid these difficulties, since a Gaussian distribution of error can be assumed in the intensities but not the amplitudes. However, errors in intensities may not only be the result of counting statistics, but may have additional contributions from factors such as crystal disorder and motion of the molecules in the lattice during data collection.

Nevertheless, the problem of how to treat weak reflections remains. Some of the measured intensities will be negative, as a result of statistical errors of observation, and the proportion of such measurements will be relatively large for weakly diffracting macromolecular structures, especially at atomic resolution. This is less important for intensity-based likelihood than for the amplitude-based approach. French & Wilson (1978) have given a Bayesian approach for the derivation of structure-factor amplitudes from intensities using Wilson's distribution (Wilson, 1942) as a prior, but there is room for improvement in this approach. Firstly, the Wilson distribution could be upgraded using the scaling techniques suggested by Blessing (1997) and Cowtan &

Main (1998), and secondly, information about effects such as pseudosymmetry could be exploited.

Another argument for the use of intensities rather than amplitudes is relevant to least squares, where the derivative for amplitude-based refinement with respect to $F_{\rm calc}$ is singular when $F_{\rm calc}$ is equal to zero (Schwarzenbach *et al.*, 1995). This is not the case for intensity-based least squares. In applying maximum likelihood, this problem does not arise (Pannu & Read, 1996; Murshudov *et al.*, 1997).

Finally, while there may be some advantages in refining against intensities, Fourier syntheses always require structure-factor amplitudes.

18.4.4.2. Restraints on coordinates and ADPs

For a good small-molecule crystal the experimental X-ray data extend to ~0.8 Å spacing and the structure can be refined against the X-ray data alone. The resulting accuracy of the atomic coordinates will generally be better than 0.01 Å. However, even for small-molecule structures, disordered regions require the imposition of stereochemical restraints (or constraints) if the chemical integrity is to be preserved and the ADPs are to be realistic.

The typical situation for protein crystals is quite different, with atomic resolution being the exception rather than the rule. Thus, for proteins the geometry of the atomic model needs to be restrained, both in terms of geometry and ADPs. The geometric target values have been established from a set of amino-acid and small-peptide structures (see Chapter 18.3 by Engh & Huber), for which the bond-length r.m.s.d. is about 0.02 Å. In the present context, we restrict the discussion to bond lengths, but this is representative of the other restraints. Clearly, the relative contribution of the X-ray data and the restraints on the final parameters varies as a function of resolution. The restraints dominate at low resolution, while by the time 0.8 Å spacing is achieved, the restraints will be essentially irrelevant for well ordered regions. The imposition of bond-length restraints with target deviations of ~0.02 Å means that the distribution of bond lengths in the final model will be of the same order, independent of the resolution of the X-ray data. However, this must not be taken to imply that the accuracy of the atomic parameters is invariant with the overall resolution and, more importantly, the atomic displacement. To be explicit, the accuracy of the atomic positions decreases (1) as the resolution becomes worse (*i.e.*, the number of X-ray observations decreases) and (2) as the ADPs become larger. While this should be obvious to the practicing crystallographer, it may not be so apparent to the less expert user of the PDB (Wlodawer *et al.*, 2008).

Jaskolski *et al.* (2007) analysed ten structures from the PDB refined at ultra-high (better than 0.8 Å) resolution to investigate appropriate geometrical restraints. They confirmed the general correctness of values in the Engh & Huber dictionary and showed that the mean observed deviations in these ten structures from the target bond lengths were indeed roughly 0.02 Å. They therefore postulated that 0.02 Å was an appropriate value to use in applying stereochemical restraints to protein structures in general. There has been some dispute about this value (Tickle, 2007) but we believe it to be appropriate. A more detailed analysis of this issue has been performed, suggesting that target values differ depending on the structural context (Karplus *et al.*, 2008); this may lead to some fine adjustments in the target dictionary, as predicted earlier (EU 3-D Validation Network, 1998).

In analogy to the geometrical restraints based on the Engh & Huber dictionary, anisotropic ADP restraints were established in the *SHELX* program suite (Sheldrick, 2008). For example, they prevent atoms from becoming unrealistically anisotropic and restrain the shapes of the ellipsoids of bonded atoms to be not too dissimilar. Riding hydrogen atoms are assigned constrained isotropic ADPs based on those of the parent atoms.

A more theoretical justification for use of restraints is that refinement can be considered as Bayesian estimation. From this point of view, all available and usable prior knowledge should be exploited, as it should not harm the parameter estimation during refinement. Bayesian estimation shows asymptotic behaviour (Box & Tiao, 1973), *i.e.*, when the number of observations becomes large, the experimental data override the prior knowledge. In this sense, the purpose of the experiment is to enhance our knowledge about the molecule, and the procedure should be cumulative, *i.e.*, the result of the old experiment should serve as prior knowledge for the design and treatment of new experiments (Box & Tiao, 1973; Stuart *et al.*, 1999; O'Hagan, 1994). However, there are problems in using restraints. For example, the probability distribution reflecting the degree of belief in the restraints is not good enough. Use of a Gaussian approximation to distributions of distances, angles and other geometric properties has not been justified. Firstly, the distribution of geometric parameters depends strongly on ADPs. Secondly, different geometric parameters are correlated. Thirdly, many geometric parameters (*e.g.* bond angles, torsion angles) are dependent on the conformation, configuration and environment of the molecule in question (Karplus *et al.*, 2008; Gelbin *et al.*, 1996). This problem should be the subject of further investigation.

In summary, the atomic resolution structures to date confirm that a mean deviation of bond lengths from target values of 0.02 Å (and comparable values for other restraint types) is appropriate, but may be subject to minor adjustments. These levels of restraint should be applied at all resolutions: the stereochemistry should be neither over- nor under-restrained.

18.4.4.3. Partial occupancy

It may be necessary to refine one additional parameter, the occupancy factor of an atomic site, for structures possessing regions that are spatially or temporally disordered, with some atoms lying in more than one discrete site. The sum of the occupancies for alternative individual sites of a protein atom must be 1.0.

For macromolecules, the occupancy factor is important in several situations, including the following:

(1) when a protein or ligand atom is present in all molecules in the lattice, but can lie in more than one position due to alternative conformations;
(2) for the solvent region, where there may be overlapping and mutually exclusive solvent networks;
(3) when ligand-binding sites are only partially occupied due to weak binding constants, and the structures represent a mixture of native enzyme with associated solvent and the complex structure;
(4) when there is a mixture of protein residues in the crystal, due to inhomogeneity of the sample arising from polymorphism, a mixture of mutant and wild-type protein, or other causes.

Unfortunately, the occupancy parameter is highly correlated with the ADP, and it is difficult to model these two parameters at resolutions less than atomic. Even at atomic resolution, it can

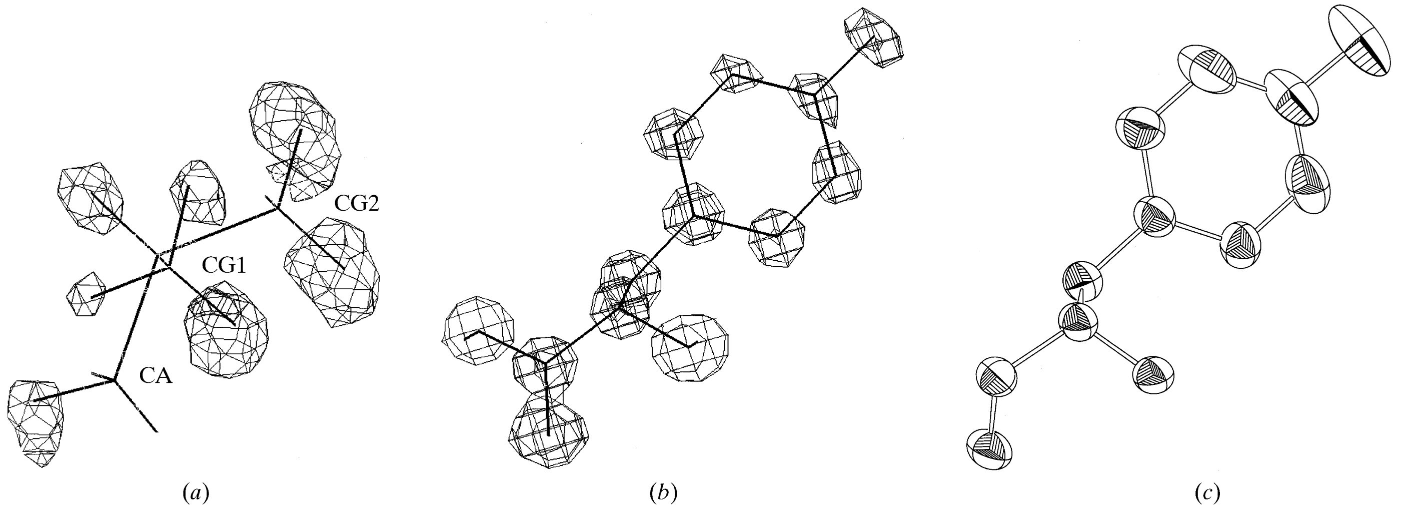

Figure 18.4.5.1
(*a*), (*b*) Representative electron-density maps for the refinement of *Clostridium acidurici* ferredoxin at 0.94 Å resolution (Dauter, Wilson *et al.*, 1997). (*a*) The density for hydrogen atoms (at 3σ) omitted from the structure-factor calculation for Val42. (*b*) The $(2F_o - F_c)$ density for Tyr30, contoured at 3σ. (*c*) The thermal ellipsoids corresponding to (*b*), drawn at the 33% probability level using *ORTEP*II (Johnson, 1976). There is a clear correlation between the density in (*b*) and the ellipsoids in (*c*), showing increased displacement towards the end of the side chain, particularly in the plane of the phenyl ring.

prove difficult to refine the occupancy satisfactorily with statistical certainty.

18.4.4.4. Validation of extra parameters during the refinement process

The introduction of additional parameters into the model always results in a reduction in the least-squares or maximum-likelihood residual – in crystallographic terms, the *R* factor. However, the statistical significance of this reduction is not always clear, since this simultaneously reduces the observation-to-parameter ratio. It is therefore important to validate the significance of the introduction of further parameters into the model on a statistical basis.

Brünger (1992*a*) introduced the concept of statistical cross validation to evaluate the significance of introducing extra features into the atomic model. For this, a small and randomly distributed subset of the experimental observations is excluded from the refinement procedure, and the residual against this subset of reflections is termed $R_{\rm free}$. It is generally sufficient to include about 1000 reflections in the $R_{\rm free}$ subset; further increase in this number provides little, if any, statistical advantage but diminishes the power of the minimization procedure. For atomic resolution structures, cross validation is important in establishing whether the introduction of an additional type of feature to the model (with its associated increase in parameters) is justified. There are two limitations to this. Firstly, if $R_{\rm free}$ shows zero or minimal decrease compared to that in the *R* factor, the significance remains unclear. Secondly, the introduction of individual features, for example the partial occupancy of five water molecules, can provide only a very small change in $R_{\rm free}$, which will be impossible to substantiate. To recapitulate, at atomic resolution the prime use of cross validation is in establishing protocols with regard to extended sets of parameter types. The sets thus defined will depend on the quality of the data.

In the final analysis, validation of individual features depends on the electron density, and Fourier maps must be judiciously inspected. Nevertheless, this remains a somewhat subjective approach and is in practice intractable for extensive sets of parameters, such as the occupancies and ADPs of all solvent sites. For the latter, automated procedures, which are being developed at present, are an absolute necessity, but they may not be optimal in the final stages of structure analysis, and visual inspection of the model and density is often needed.

The problems of limited data and reparameterization of the model remain. At high resolution, reparameterization means having the same number of atoms, but changing the number of parameters to increase their statistical significance, for example switching from an anisotropic to an isotropic atomic model or *vice versa*. In contrast, when reparameterization is applied at low resolution, this usually involves constraints, *i.e.*, a reduction in the number of independent atoms, but this is not an ideal procedure, as real chemical entities of the model are sacrificed. Reducing the number of independent atoms will inevitably result in disagreement between the experiment and model, which in turn will affect the precision of other parameters. It would be more appropriate to reduce the number of parameters without sacrificing the number of atoms, for example by describing the model in torsion-angle space. Water poses a particular problem, as at low as well as at high resolution the water molecules cannot all be described as discrete atoms. Algorithms are needed to describe them as a continuous model with only a few parameters. In the simplest model, the solvent can be described as a constant electron density.

18.4.5. Features in the refined model

All features of the refined model are more accurately defined if the data extend to higher resolution (Fig. 18.4.5.1). In this section, those features that are especially enhanced in an atomic resolution analysis are described. Introduction of an additional feature to the model should be assessed by the use of cross- or self-validation tools: only then can the significance of the parameters added to the model be substantiated.

18.4.5.1. Hydrogen atoms

Hydrogen atoms possess only a single electron and therefore have low electron density and are relatively poorly defined in X-ray studies. They play central roles in the function of proteins, but at the traditional resolution limits of macromolecular structure analyses their positions can only be inferred rather than defined from the experimental data. Indeed, even at a resolution of 2.5 Å, hydrogen atoms should be included in the refined model, as their exclusion biases the position of the heavier atoms, but with their 'riding' positions fixed by those of the parent atoms.

As for small structures, independent refinement of hydrogen-atom positions is not always warranted, even by atomic resolution data, and hydrogen atoms are rather attached as riding rigidly on the positions of the parent atoms. Nevertheless, atomic resolution data allow the experimental confirmation of the positions of many of the hydrogen atoms in the electron-density maps, as they do account for one-sixth of the diffracting power of a carbon atom. Inspection of the maps can in principle allow the identification of (1) the presence or absence of hydrogen atoms on key residues, such as histidine, aspartate and glutamate or on ligands, and (2) the correct location of hydrogen atoms where more than one position is possible, such as in the hydroxyl groups of serine, threonine or tyrosine.

The correct placement of hydrogen atoms riding on their parent atoms involves computation of the appropriate position after each cycle of refinement. This is done automatically by programs such as *SHELXL*, *REFMAC* or *PHENIX.REFINE*. For rigid groups such as the NH amide, aromatic rings, $-CH_2-$ or $=CH-$, the position is accurately defined by the bonding scheme. For groups such as methyl CH_3 or OH, the position is not absolutely defined, and the software is required to make judgmental decisions. For example, *SHELXL* offers the opportunity to inspect the maximum density on a circular Fourier synthesis for optimal positioning. The bond length is fixed according to results from a small-molecule database. The location of hydrogen atoms on polar atoms can be assisted by software that analyses the local hydrogen-bonding networks; this involves maximization of the hydrogen-bonding potential of the relevant groups. Sheldrick advocates assigning ADP values to riding hydrogen atoms of 1.2 times that of the parent atom, or 1.5 times in the case of methyl and similar entities.

18.4.5.2. *Anisotropic atomic displacement parameters*

Refinement of an isotropic model involves four independent parameters per atom, three positional and one isotropic ADP. In contrast, an anisotropic model requires nine parameters per atom, with the anisotropic atomic displacement described by an ellipsoid represented by six parameters. At 1 Å resolution, the data certainly justify an anisotropic atomic model. Extension of the model from isotropic to anisotropic should generally result in a reduction in the R factor of the order of 5–6% and a comparable drop in $R_{\rm free}$. As a consequence of the diminution of the observable-to-parameter ratio, the R factor at all resolutions will drop by a similar amount; however, $R_{\rm free}$ will not. Experience shows that at 2 Å or less there is no drop in $R_{\rm free}$, and an anisotropic model is totally unsupported by the data. At intermediate resolutions, the result depends on the data quality and completeness. At lower resolution, to account for anisotropy of the atoms, the overall motion of molecules or domains can be refined using translation/libration/screw (TLS) parameters (Schomaker & Trueblood, 1968).

Until the end of the 1990s, anisotropic ADPs had only been handled by programs originally developed for small-molecule analysis, which use conventional algebraic computations of the calculated structure-factor amplitudes, *SHELXL* being a prime example. A limitation of this approach is the substantial computation time required. The use of fast-Fourier-transform algorithms for the structure-factor calculation leads to a significant saving in time (Murshudov *et al.*, 1999). Anisotropic modelling of the individual ADPs is essential if the thermal vibration is to be analysed in terms of coordinated motion of the whole molecule or of domains (Schomaker & Trueblood, 1968). Painter & Merritt (2006) have provided a means of analysing refined models to suggest appropriate TLS groupings.

18.4.5.3. *Alternative conformations*

Proteins are not rigid units with a single allowed conformation. *In vivo* they spontaneously fold from a linear sequence of amino acids to provide a three-dimensional phenotype that may exhibit substantial flexibility, which can play a central role in biological function, for example in the induced fit of an enzyme by a substrate or in allosteric conformational changes. Flexibility is reflected in the nature of the protein crystals, in particular the presence of regions of disordered solvent between neighbouring macromolecules in the lattice (see Section 18.4.5.6).

The structure tends to be highly ordered at the core of the protein, or more properly, at the core of the individual domains. Atoms in these regions in the most ordered protein crystals have ADP values comparable to those of small molecules, reflecting the fact that they are, in essence, closely packed by surrounding protein. In general, as one moves towards the surface of the protein, the situation becomes increasingly fluid. Side chains and even limited stretches of the main chain may show two (or multiple) conformations. These may be significant for the biological function of the protein.

The ability to model the alternative conformations is highly resolution dependent. At atomic resolution, the occupancy of two alternative but well defined conformations can be refined to an accuracy of about 5%, thus second conformations can be seen, provided that their occupancy is about 10% or higher. The limited number of proteins for which atomic resolution structures are available suggest that up to 20% of the 'ordered residues' show multiple conformations. This confers even further complexity on the description of the protein model. A constraint can be imposed on residues with multiple conformations: namely that the sum of all the alternatives must be 1.0. Protein regions (whether they are side- or main-chain regions) with alternative conformations and partial occupancy can form clusters in the unit cell with complementary occupancy. This often coincides with alternative sets of solvent sites, which should also be refined with complementary occupancies.

The atoms in two alternative conformations occupy independent and discrete sites in the lattice, about which each vibrates. However, if the spacing between two sites is small and the vibration of each is large, then it becomes impossible to differentiate a single site with high anisotropy from two separate sites. There is no absolute rule for such cases: programs such as *SHELXL* place an upper limit on the anisotropy and then suggest splitting the atom over two sites. Some regions can show even higher levels of disorder, with no electron density being visible for their constituent atoms. Such fully disordered regions do not contribute to the diffraction at high resolution, and the definition of their location will not be improved with atomic resolution data.

18.4.5.4. Ordered solvent water

A protein crystal typically contains ~50% aqueous solvent. This is roughly divided into two separate zones. The first is a set of highly ordered sites close to the surface of the protein. The second, lying remote from the protein surface, is essentially composed of fluid water, with no order between different unit cells.

At room temperature, the solvent sites around the surface are assumed to be in dynamic equilibrium with the surrounding fluid, as for a protein in solution. Nevertheless, the observation of apparently ordered solvent sites on the surface indicates that these are occupied most of the time. The waters are organized in hydrogen-bonded networks, both to the protein and with one another. The most highly ordered water sites lie in the first solvent shell, where at least one contact is made directly to the protein. For the second and subsequent shells the degree of order diminishes: such shells form an intermediate grey level between the ordered protein and the totally disordered fluid. Indeed, the flexible residues on the surface form part of the continuum between a solid and liquid phase.

In the ordered region, the solvent structure can be modelled by discrete sites whose positional parameters and ADPs can be refined. For sites with low ADPs, the refinement is stable and their behaviour is well defined. As the ADPs increase, or more likely the associated occupancy in a particular site falls, the behaviour deteriorates, until finally the existence of the site becomes dubious. There is no hard cutoff for the reality of a weak solvent site. However, the number and significance of solvent sites are increased by atomic resolution data. Despite the fact that the waters contribute only weakly to the high-resolution terms, the improved accuracy of the rest of the structure and the reduction of noise due to the high resolution mean that their positions become better defined.

Indeed, the occupancy of some solvent sites can be refined if the resolution is sufficient, or at least their fractional occupancy can be estimated and kept fixed (Walsh *et al.*, 1998). This leads to the possibility of defining overlapping water networks with alternative hydrogen-bonding schemes. This can be a most time-consuming step in atomic resolution refinement, and a trade-off finally has to be made between the relevance of any improvement in the model and the time spent.

18.4.5.5. Automatic location of water sites

The protein itself has a clearly defined chemical structure, and the number of atoms to be positioned and how they are bonded to one another are known at the start of model building. The solvent region is in marked contrast to this, as the number of ordered water sites is not known *a priori*, and the distances between them are less well defined, their occupancy is uncertain, and there may be overlapping networks of partially occupied solvent sites. Those of low occupancy lie at the level of significance of the Fourier maps.

Selection of partially occupied solvent sites poses a most cumbersome problem in the modelling over and above that of the macromolecule itself, and can be highly subjective and very time consuming. Improved resolution of the data reveals additional weak or partially occupied solvent sites, which generally do not behave well during refinement. Water atoms modelled into relatively weak peaks in electron density tend to drift out of the density during refinement due to the inaccurate gradients that define their positions.

Given the huge number of water sites in question, automatic and at least semi-objective protocols are required. Several procedures have been developed for the automated identification of water sites during refinement [*inter alia ARP* (Lamzin & Wilson, 1997) and *SHELXL* (Sheldrick & Schneider, 1997)] and others allow selective inspection of such sites using graphics [such as *O* (Jones *et al.*, 1991) and *COOT* (Emsley & Cowtan, 2004)]. These depend on a combination of peak height in the density map and geometric considerations. However, these programs are currently optimized for structures at more typical resolutions, and future efforts could be made to adapt them for atomic resolution structures with overlapping water networks and other high levels of detail.

18.4.5.6. Bulk solvent and the low-resolution reflections

As stated in Section 18.4.5.3 and first reviewed by Matthews (1968) and more recently by Andersson & Hovmöller (1998), macromolecular crystals contain substantial regions of totally disordered, or bulk, aqueous solvent, in addition to those solvent molecules bound to the surface. The average electron density of the crystal volume occupied by protein is 1.35 g cm^{-3} (according to Matthews) or 1.22 g cm^{-3} (according to Andersson & Hovmöller), while that of water is 1.0 g cm^{-3}. This is because the atoms are more closely packed within the protein, as they are connected by covalent bonds, while in solvent regions they form sets of hydrogen-bonded networks.

To model both the solvent and protein regions of the crystal appropriately, it is necessary to have a satisfactory representation of the bulk solvent. The high *R* factors generally observed for most proteins for the low-resolution shells are in part symptomatic of the poor modelling of this feature or of systematic errors in the recording of the intensities of the low-angle reflections. For atomic resolution structures, the *R* factor can fall to values as low as 6–7% around 3–5 Å resolution. However, in lower-resolution shells it then rises steadily, often reaching values in the range of 20–40% below 10 Å. These observations indicate serious deficiencies in our current models or data.

The poorest approach is to ignore bulk solvent and assign zero electron density to those regions where there are no discrete atomic sites, as this leads to a severe discontinuum. An improved approach is to assign a constant value of the electron density to all points of the Fourier transform that are not covered by the discrete, ordered sites. This provides substantial reduction in the *R* factor for low-resolution shells of the order of 10% and requires the introduction of only one extra parameter to the least-squares minimization. An improvement of this simplistic model is the introduction of a second parameter, $B_{\rm sol}$, described by

$$\text{scale} = k_0 \exp(-B_0 s^2/4)[1 - k_{\rm sol} \exp(-B_{\rm sol} s^2/4)], \qquad (18.4.5.1)$$

where k_0 and B_0 are the scale factors for the protein, and $k_{\rm sol}$ and $B_{\rm sol}$ are the equivalent parameters for the bulk solvent (Tronrud, 1997). In effect, this provides a resolution-dependent smoothing of the interface contribution, rather than an overall term applied equally to all the data. The physical basis of this is discussed by Tronrud and implemented in several programs, for example *SHELXL*, *REFMAC* and *PHENIX.REFINE* (Fig. 18.4.5.2).

Another approach (Jiang & Brunger, 1994) to account for the effect of solvent is as follows: (1) calculate the mask covering the atoms in the crystal; (2) include a constant value for the electron density in the region not covered by the mask; (3) calculate structure factors from the solvent region; and (4) compute a total structure by applying the appropriate scale to the solvent contribution:

$$F_{\text{total}} = F_{\text{prot}} + k_m \exp(-B_m s^2/4) F_{\text{mask}}, \qquad (18.4.5.2)$$

where k_m and B_m are the scale and temperature factor for the solvent contribution, and F_{total}, F_{prot} and F_{mask} are the complex structure factors corresponding to the combined contribution from the protein and solvent region. The scale and B values are usually refined iteratively to find the best match to the observed structure factors, and are implemented in *CNS*, *REFMAC* and *PHENIX.REFINE*.

Nevertheless, there remain severe problems in the modelling of the interface. The border between the two regions is not abrupt, as there is a smooth and continuous change from the region with fully occupied, discrete sites to one which is truly fluid, but this passes through a volume with an increasing level of dynamic disorder and associated partial occupancy. Modelling of this region poses major problems, as described above, and the definition of disordered sites with low occupancy remains difficult even at atomic resolution. At which stage the occupancy and associated ADP can be defined with confidence is not yet an objective decision. In addition, refinement and modelling at this level of detail is very time consuming in terms of human intervention.

18.4.5.7. *Metal ions and other ligands in the solvent*

In general, proteins are crystallized from aqueous solutions which contain various additives, such as anions or cations (especially metals), organic solvents, including those used as cryoprotectants, and other ligands. Some of these may bind in specific or indeed non-specific sites in the ordered solvent shell, in addition to any functional binding sites of the protein. To identify such entities at limited resolution is often impossible, as the range of expected ADPs is large and there is very poor discrimination in the appearance of such sites and of water in the electron density. Atomic resolution assists in resolving ambiguities, as the interatomic distances, ADPs and occupancies are all better defined.

For metal ions, two additional criteria can be invoked. Firstly, the coordination geometry, with well defined bond lengths and angles, provides an indication of the identity of the ion, as different metals have different preferred ligand environments (Harding, 1999, 2006). The bond-valence approach is also applicable (Müller *et al.*, 2003). In addition, the value of the refined ADP and/or occupancy is helpful. Secondly, the anomalous signal in the data should reveal the presence of metal and some other non-water sites in the solvent through computation of the anomalous difference synthesis (Dauter & Dauter, 1999). This emphasizes the need to retain the anomalous signal during the collection and reduction of native data. While these approaches can be applied at lower resolution, they both become much more powerful at atomic resolution.

The presence of bound organic ligands has become especially relevant since the advent of cryogenic freezing. Compounds such as ethylene glycol and glycerol possess a number of functional hydrogen-bonding groups that can attach to sites on the protein in a defined way. Indeed, these may often bind in the active sites of enzymes such as glycosyl hydrolases, where they mimic the hydroxyl groups of the sugar substrate. It is most important to identify such moieties properly, particularly if substrate studies are to be planned successfully.

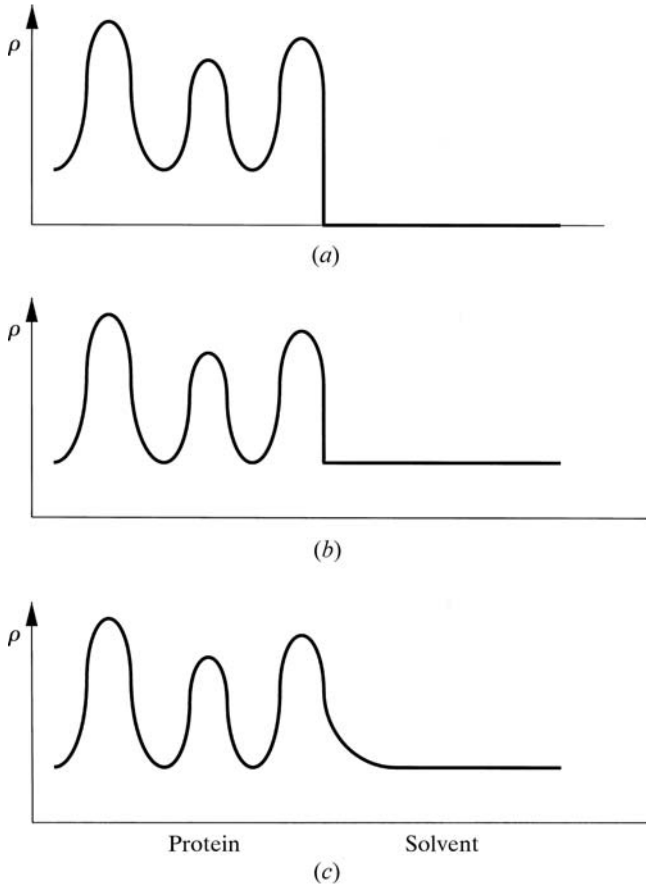

Figure 18.4.5.2
Schematic representation of the bulk-solvent models described in the text. (*a*) No bulk-solvent correction, *i.e.* solvent density set to zero. (*b*) Constant level of solvent outside the macromolecule and ordered water envelope. Here, sharp edge effects remain. (*c*) The model as in (*b*), but smoothed at the edge of a macromolecule, equivalent to the application of a *B* value to the solvent model.

18.4.5.8. *Deformation density*

X-ray structures are generally modelled using the spherical-atom approximation for the scattering, which ignores the deviation from sphericity of the outer bonding and lone-pair electrons. Extensive studies over a long period have confirmed that the so-called deformation density, representing deviation from this spherical model, can be determined experimentally using data to very high resolution, usually from 0.8 to 0.5 Å. An excellent review of this field has been provided by Coppens (1997). The observed deviations can be compared with those expected from the available theories of chemical bonding and the densities derived therefrom.

The application of atomic resolution analysis to proteins allowed the observation of the deformation density in macromolecules (Lamzin *et al.*, 1999). Data for two proteins were analysed: crambin (molecular weight 6 kDa) at 0.67 Å resolution and a subtilisin (molecular weight 30 kDa) at 0.9 Å resolution. Significant and interpretable deformation density could not be observed for the individual residues. However, on averaging the density over 40 peptide units for crambin and more than 250 for the subtilisin, the deformation density within the peptide unit was clearly visible and could be related to the expected bonding features in these units. This shows the real power of atomic resolution crystallography, which can reveal features containing no more than 0.2 e Å^{-3}.

Deformation density studies are now being applied to many polypeptides (Jelsch *et al.*, 1998; Koritsanszky *et al.*, 2002; Pichon-

Pesme *et al.*, 2004; Afonine *et al.*, 2007; Zarychta *et al.*, 2007). It has been observed that details of deformation densities are most clearly revealed when only the highest resolution (so-called high order) terms are included in the refinement and the Fourier maps (Coppens, 1997). This is reported to result from the deconvolution of the effects of the anisotropic ADPs, which can to some extent take up the fine features corresponding to the deformation density (bonding electrons and lone pairs). After proper modelling of the deformation density features, the overall model is refined against all the data.

18.4.6. Quality assessment of the model

The refinement of proteins at resolutions lower than atomic depends upon the use of restraints on the geometry and ADPs. The almost exclusively used library of target geometric restraints for refinement and validation of protein structures (Chapter 18.3) is derived from structures of amino acids and peptides in the Cambridge Crystallographic Data Centre's small-molecule crystal structure database (Allen *et al.*, 1979). Stereochemical parameters, such as conformational angles φ, ψ, should ideally not be restrained, as they allow independent validation of the model. As stated in Section 18.4.4.2, these restraints are required even at atomic resolution to maintain the chemical integrity of flexible regions, although their impact will be limited on ordered regions.

Owing to the excess of accurate X-ray observations over parameters at atomic resolution, extensive validation of individual structures should be less challenging than for those at lower resolution. It is hard to achieve an R factor around 10% with an incorrect model. However, considerable attention needs to be given to detail and great care taken to avoid over-interpretation, especially of the flexible regions.

An analysis of eight structures determined at atomic resolution some years ago (EU 3-D Validation Network, 1998) indicated that they follow the expected rules of chemistry more closely than those of lower-resolution analyses in the PDB, confirming that atomic resolution indeed provides more precise coordinates. A subsequent analysis of ten structures at ultra-high resolution, 0.8 Å or better (Jaskolski *et al.*, 2007) confirmed these conclusions but identified a few possible adjustments to some targets. Following this analysis, Karplus *et al.* (2008) proposed that protein stereochemistry is context dependent, *e.g.* it differs in detail between α-helices and β-strands, and that this should be reflected in future target libraries. Thus, the availability of atomic resolution structures will provide a more objective basis for the construction of such libraries.

18.4.7. Relation to biological chemistry

A question arises as to what biological issues are addressed by analysis of macromolecular structures at atomic resolution. For any protein, the overall structure of its fold, and hence its homology with other proteins, can already be provided by analyses at low to medium resolution. However, proteins are the active entities of cells and carry out recognition of other macromolecules, ligand binding and catalytic roles that depend upon subtle details of chemistry, for which accurate positioning of the atoms is required. Even at atomic resolution, the accuracy of structural definition is less than what would ideally be required for the changes observed during a chemical reaction. At lower resolutions, structure–function relations require yet further extrapolation of the experimental data.

To understand the function of many macromolecules, such as enzymes, it is not sufficient to determine the structure of a single state. Alongside the native structure, those of various complexes will also be required. The differences between the states provide additional information on the functionality. For an understanding of the chemistry involved, atomic resolution has tremendous advantages in terms of accuracy, as reliable judgments can be based on the experimental data alone.

Advantages of atomic resolution include the following:

(1) The positions of all atoms that possess defined conformations are more accurately defined. This means that all bond lengths and angles in the structure have lower standard uncertainties (EU 3-D Validation Network, 1998). For regions of the molecule where the conformation is representative of the norm, this is of purely quantitative significance, but where the stereochemistry deviates from the expected value this accuracy takes on a special significance, which poses questions to the theoretical chemist. Such deviations from standard geometry often play an important role in biological function.

(2) The better the ADP definition, notably its anisotropy, the greater the insight into the static or thermal flexibility of individual regions of the molecule. Macromolecules are crucially dependent upon flexibility for properties such as induced fit in substrate or ligand recognition, allosteric responses or responses to the biological environment. More detailed definition of the position and mobility of flexible regions may be assisted by atomic resolution analysis.

(3) A few amino-acid side chains play an active role in catalysis. Those that do include histidine, aspartic and glutamic acids and serine, all through protonation–deprotonation events, and hydrogen atoms are crucial to their function. Hydrogen atoms are usually treated as riding on their parent atoms and should be included in the model, even at medium resolution. Unfortunately, those hydrogen atoms that are of interest can only rarely be treated as rigidly bonded at a predictable position. However, atomic resolution allows many hydrogen atoms to be clearly identified in the refined electron density. In addition, the presence or absence of hydrogen may be inferred by accurate estimation of the bond lengths between atoms, *e.g.* within the carboxylate groups.

(4) The relative orientation of reacting moieties is crucial to enzyme catalysis. If chemical hypotheses of mechanism are to be subjected to appropriate Popperian scrutiny (Popper, 1959), then precise definition of atomic coordinates in native and complex structures is necessary.

(5) Enzyme catalysis provides a reduction of the activation energy of the reaction, which can be achieved by distortion of the conformation of the substrate bound to the enzyme (the so-called Michaelis complex) towards the transition state or by the stabilization of the latter by the enzyme. For both, the study of complexes of inhibitors or substrate analogues at a sufficient resolution to clarify the fine detail of the structures is required.

(6) Adaptation of the enzyme to the substrate is postulated by the induced-fit theory of catalysis. The level of adjustment can be very small, and energy calculations again require that this be precisely defined.

(7) In metalloproteins, the ligand field, and hence geometry and bond lengths, around the metal ion are essential indicators of any variation in valence electrons between different states. For example, bond lengths between oxidized and reduced states of metal ions vary by the order of 0.1 Å or less, and

clear distinction between alternative oxidation states requires an accuracy only provided by atomic resolution.

Almost all atomic resolution analyses require data recorded from cryogenically frozen crystals. This does pose some problems of biological relevance, as proteins *in vivo* have adapted to operate at ambient cellular temperatures. The structure that is required is that of the protein and surrounding solvent at the corresponding temperature. The trade-off is that cryogenic structures may be better defined, but that they are only so because of the increased order of the protein and solvent at low temperature. This has to be weighed against the lack of fine detail in a medium-resolution analysis at room temperature.

A question often raised with regard to the worth of atomic resolution data concerns the effort required in refining a protein at such resolution. To define all details, such as alternative conformations, hydrogen-atom positions and solvent, is certainly time consuming, especially if an anisotropic model is adopted. However, the advantages outweigh the disadvantages, as even if a full anisotropic model is not refined to exhaustion, nevertheless all density maps will be clearer if the resolution is better, resulting in an improved definition of the features of interest.

18.4.8. Practical strategies

Pioneering work was carried out by Teeter and colleagues on crambin, using data recorded on this small and highly stable protein using a conventional diffractometer (Teeter *et al.*, 1993). Some of the earliest atomic resolution structures using data from a synchrotron source with an imaging plate detector included rubredoxin at 1.0 Å (Dauter *et al.*, 1992), ribonuclease Sa at 1.1 Å (Sevcik *et al.*, 1996) and triclinic lysozyme at 0.9 Å resolution (Walsh *et al.*, 1998), at room temperature for the rubredoxin and ribonuclease, and 100 K for the lysozyme. The strategy used involved the application of conventional restrained least-squares or maximum-likelihood techniques in the early stages of refinement, followed by switching over to *SHELXL* to introduce a full anisotropic model and riding hydrogen atoms.

Subsequent structures have almost exclusively used cryogenically vitrified crystals to minimize the effects of radiation damage on high-intensity SR beamlines. A review of the field (Dauter, 2003) reported over 100 structures at better than 1.2 Å spacing, and in January 2011 there were around 1450 such coordinate sets in the PDB.

Initially, only *SHELXL* was able to refine macromolecular structures with anisotropic ADPs, riding hydrogen atoms and appropriate stereochemical restraints. Subsequently, such options have been implemented in programs such as *REFMAC* and *PHENIX.REFINE*. The use of fast Fourier algorithms gives these programs some speed advantage over *SHELXL*, but this is now of less importance given the power of contemporary computers. The key advantage of *SHELXL* is the ability to perform full- (or at least block-) matrix inversion, and hence extract error estimates for each individual parameter.

It is not straightforward to provide hard and fast rules for the optimum strategy. The power of refinement at atomic resolution lies in the sheer number of X-ray observations which drive the minimization to a global minimum. The dangers of bias in the final model and of false minima can largely be ignored. As a guideline the following steps would seem to be a common-sense approach when data to 1.2 Å or better are available.

(1) Refine an initial isotropic model at modest resolution with one of the conventional programs to ensure the correct global minimum has been reached. This step was probably more appropriate in the days when computing resources were more limiting, and could probably be omitted today.

(2) Introduce an anisotropic model with riding hydrogen atoms using one of the maximum-likelihood programs such as *REFMAC*, *PHENIX.REFINE* or *SHELXL* (with the conjugate-gradient option), and refine against the experimental data, omitting around 1000–2000 reflections for validation by $R_{\rm free}$. It is *not* necessary to omit 5% of the data, particularly at this resolution.

(3) Complete the water model using one of the autobuild options within or associated with (*e.g. ARP/wARP* or *COOT*) the refinement program. This is an area amenable to considerable automation in the future to allow partially occupied sites and overlapping networks to be defined without user intervention.

(4) Introduce alternative conformations for the protein. Much of this is also amenable to automation, especially for the side chains, where programs such as *COOT* can already suggest likely alternate rotamers.

(5) Inspect appropriately weighted electron-density maps for features to be added, deleted or moved. This includes ligands, metal atoms, ions, cryprotectants and other additives. Current developments in programs such as *COOT* are increasingly automating this step. Software libraries that provide accurate descriptions of the ligand chemistry and geometry are essential, and are the subject of intense development. It is vital that structures are deposited in the PDB with the correct geometrical restraints. To some extent, steps (3)–(5) go in parallel, and indeed their order is not vital.

(6) Consider the *SHELXL* full-matrix option for the final refinement cycles. This will provide estimates of the accuracy of the individual parameters, not available from other programs.

(7) As a final step, run some cycles with all reflections including those previously used for $R_{\rm free}$, but without changing the model parameters. At all stages, it will remain necessary to impose restraints to avoid poor behaviour of any flexible regions. As the resolution goes beyond 1 Å, the effect of such restraints on good parts of the structure becomes minimal.

In summary, at atomic resolution models require special attention to detail, reflecting the wealth of information with regard to features such as alternative conformations of both side and main chains, and extensive ordered water structure often with partial occupancy and overlapping networks. With the present software, this can be a lengthy operation, and indeed this can persuade some scientists to work at lower, less informative, resolution to speed up and simplify the analysis. Many of the presently tedious manual tasks in terms of model construction are, however, amenable to extensive automation. As the number of atomic resolution structures increases, we can expect the refinement and modelling process to be greatly simplified with new software algorithms.

Chapter 18.5. Coordinate uncertainty

D. W. J. Cruickshank

18.5.1. Introduction

18.5.1.1. Background

Even in 1967 when the first few protein structures had been solved, it would have been hard to imagine a time when the best protein structures would be determined with a precision approaching that of small molecules. That time was reached during the 1990s. Consequently, the methods for the assessment of the precision of small molecules can be extended to good-quality protein structures.

The key idea is simply stated. At the conclusion and full convergence of a least-squares or equivalent refinement, *the estimated variances and covariances of the parameters may be obtained through the inversion of the least-squares full matrix.*

The inversion of the full matrix for a large protein is a gigantic computational task, but it is being accomplished in a rising number of cases. Alternatively, approximations may be sought. Often these can be no more than rough order-of-magnitude estimates. Some of these approximations are considered below.

Caveat. Quite apart from their large numbers of atoms, protein structures show features differing from those of well ordered small-molecule structures. Protein crystals contain large amounts of solvent, much of it not well ordered. Parts of the protein chain may be floppy or disordered. All natural protein crystals are noncentrosymmetric, hence the simplifications of error assessment for centrosymmetric structures are inapplicable. The effects of incomplete modelling of disorder on phase angles, and thus on parameter errors, are not addressed explicitly in the following analysis. Nor does this analysis address the quite different problem of possible gross errors or misplacements in a structure, other than by their indication through high B values or high coordinate standard uncertainties. These various difficulties are, of course, reflected in the values of $\Delta|F|$ used in the precision estimates.

On the problems of structure validation see Part 21 of this volume and Dodson (1998).

Some structure determinations do make a first-order correction for the effects of disordered solvent on phase angles by application of Babinet's principle of complementarity (Langridge *et al.*, 1960; Moews & Kretsinger, 1975; Tronrud, 1997). Babinet's principle follows from the fact that if $\rho(\mathbf{x})$ is constant throughout the cell, then $F(\mathbf{h}) = 0$, except for $F(\mathbf{0})$. Consequently, if the cell is divided into two regions C and D, $F_C(\mathbf{h}) = -F_D(\mathbf{h})$. Thus if D is a region of disordered solvent, $F_D(\mathbf{h})$ can be estimated from $-F_C(\mathbf{h})$. A first approximation to a disordered model may be obtained by placing negative point-atoms with very high Debye B values at all the ordered sites in region C. This procedure provides some correction for very low resolution planes. Alternatively, corrections are sometimes made by a mask bulk solvent model (Jiang & Brünger, 1994).

The application of restraints in protein refinement does not affect the key idea about the method of error estimation. A simple model for restrained refinement is analysed in Section 18.5.3, and the effect of restraints is discussed in Section 18.5.4 and later.

Much of the material in this chapter is drawn from a Topical Review published in *Acta Crystallographica*, Section D (Cruickshank, 1999).

Protein structures exhibiting noncrystallographic symmetry are not considered in this chapter.

18.5.1.2. Accuracy and precision

A distinction should be made between the terms *accuracy* and *precision.* A single measurement of the magnitude of a quantity differs by error from its unknown true value λ. In statistical theory (Cruickshank, 1959), the fundamental supposition made about errors is that, for a given experimental procedure, the possible results of an experiment define the probability density function $f(x)$ of a *random variable.* Both the true value λ and the probability density $f(x)$ are unknown. The problem of assessing the accuracy of a measurement is thus the double problem of estimating $f(x)$ and of assuming a relation between $f(x)$ and λ.

Precision relates to the function $f(x)$ and its spread.

The problem of what relationship to assume between $f(x)$ and the true value λ is more subtle, involving particularly the question of *systematic errors.* The usual procedure, after correcting for known systematic errors, is to suppose that some typical property of $f(x)$, often the mean, is the value of λ. No repetition of the same experiment will ever reveal the systematic errors, so statistical estimates of precision take into account only random errors. Empirically, systematic errors can be detected only by remeasuring the quantity with a different technique.

Care is needed in reading older papers. The word accuracy was sometimes intended to cover both random and systematic errors, or it may cover only random errors in the above sense of precision (known systematic errors having been corrected).

In recent years, the well established term *estimated standard deviation* (e.s.d.) has been replaced by the term *standard uncertainty* (s.u.). (See Section 18.5.2.3 on statistical descriptors.)

18.5.1.3. Effect of atomic displacement parameters (or 'temperature factors')

It is useful to begin with a reminder that the Debye $B = 8\pi^2\langle u^2\rangle$, where u is the atomic displacement parameter. If $B = 80$ Å^2, the r.m.s. amplitude is 1.01 Å. The centroid of an atom with such a B is unlikely to be precisely determined. For $B = 40$ Å^2, the 0.71 Å r.m.s. amplitude of an atom is approximately half a C—N bond length. For $B = 20$ Å^2, the amplitude is 0.50 Å. Even for $B = 5$ Å^2, the amplitude is 0.25 Å. The size of the atomic displacement amplitudes should always be borne in mind when considering the precision of the position of the centroid of an atom.

Scattering power depends on $\exp[-2B(\sin\theta/\lambda)^2] = \exp[-B/(2d^2)]$. For $B = 20$ Å^2 and $d = 4$, 2 or 1 Å, this factor is 0.54, 0.08 or 0.0001. For $d = 2$ Å and $B = 5$, 20 or 80 Å^2, the factor is again 0.54, 0.08 or 0.0001. The scattering power of an atom thus depends very strongly on B and on the resolution $d = 1/s = \lambda/2\sin\theta$. Scattering at high resolution (low d) is dominated by atoms with low B.

Copyright © 2012 International Union of Crystallography

An immediate consequence of the strong dependence of scattering power on B is that the standard uncertainties of atomic coordinates also depend very strongly on B, especially between atoms of different B within the same structure.

[An IUCr Subcommittee on Atomic Displacement Parameter Nomenclature (Trueblood *et al.*, 1996) has recommended that the phrase 'temperature factor', though widely used in the past, should be avoided on account of several ambiguities in its meaning and usage. The Subcommittee also discourages the use of B and the anisotropic tensor $\mathbf{B}$ in favour of $\langle u^2 \rangle$ and $\mathbf{U}$, on the grounds that the latter have a more direct physical significance. The present author concurs (Cruickshank, 1956, 1965). However, as the use of B or $B_{\rm eq}$ is currently so widespread in biomolecular crystallography, this chapter has been written in terms of B.]

18.5.2. The least-squares method

18.5.2.1. *The normal equations*

In the unrestrained least-squares method, the residual

$$R = \sum_3 w(hkl)\Delta^2(hkl) \tag{18.5.2.1}$$

is minimized, where Δ is either $|F_o| - |F_c|$ for R_1 or $|F_o|^2 - |F_c|^2$ for R_2, and $w(hkl)$ is chosen appropriately. The summation is over crystallographically independent planes.

When R is a minimum with respect to the parameter u_j, $\partial R/\partial u_j = 0$, *i.e.*,

$$\sum_3 w\Delta(\partial\Delta/\partial u_j) = 0. \tag{18.5.2.2}$$

For R_1, $\partial\Delta/\partial u_j = -\partial|F_c|/\partial u_j$; for R_2, $\partial\Delta/\partial u_j = -2|F_c|\partial|F_c|/\partial u_j$. The n parameters have to be varied until the n conditions (18.5.2.2) are satisfied. For a trial set of the u_j close to the correct values, we may expand Δ as a function of the parameters by a Taylor series to the first order. Thus for R_1,

$$\Delta(\mathbf{u} + \mathbf{e}) = \Delta(\mathbf{u}) - \sum_i \varepsilon_i(\partial|F_c|/\partial u_i), \tag{18.5.2.3}$$

where ε_i is a small change in the parameter u_i, and $\mathbf{u}$ and $\mathbf{e}$ represent the whole sets of parameters and changes. The minus sign occurs before the summation, since $\Delta = |F_o| - |F_c|$, and the changes in $|F_c|$ are being considered.

Substituting (18.5.2.3) in (18.5.2.2), we get the *normal equations* for R_1,

$$\begin{aligned}\sum_i \varepsilon_i \left[\sum_3 w(\partial|F_c|/\partial u_i)(\partial|F_c|/\partial u_j)\right]&\\ = \sum_3 w\Delta(\partial|F_c|/\partial u_j).&\end{aligned} \tag{18.5.2.4}$$

There are n of these equations for $j = 1, \ldots, n$ to determine the n unknown ε_j.

For R_2 the normal equations are

$$\begin{aligned}\sum_i \varepsilon_i \left[\sum_3 w(\partial|F_c|^2/\partial u_i)(\partial|F_c|^2/\partial u_j)\right]&\\ = \sum_3 w\Delta(\partial|F_c|^2/\partial u_j).&\end{aligned} \tag{18.5.2.5}$$

Both forms of the normal equations can be abbreviated to

$$\sum_i \varepsilon_i a_{ij} = b_j. \tag{18.5.2.6}$$

For the values of $\partial|F_c|/\partial u_j$ for common parameters see, *e.g.*, Cruickshank (1970).

Some important points in the derivation of the standard uncertainties of the refined parameters can be most easily understood if we suppose that the matrix a_{ij} can be approximated by its diagonal elements. Each parameter is then determined by a single equation of the form

$$\varepsilon_i \sum_3 wg^2 = \sum_3 wg\Delta, \tag{18.5.2.7}$$

where $g = \partial|F_c|/\partial u_i$ or $\partial|F_c|^2/\partial u_i$. Hence

$$\varepsilon_i = \left(\sum_3 wg\Delta\right) \bigg/ \left(\sum_3 wg^2\right). \tag{18.5.2.8}$$

At the conclusion of the refinement, when R is a minimum, the variance (square of the s.u.) of the parameter u_i due to uncertainties in the Δ's is

$$\sigma_i^2 = \left[\sum_3 w^2 g^2 \sigma^2(F)\right] \bigg/ \left(\sum_3 wg^2\right)^2. \tag{18.5.2.9}$$

If the weights have been chosen as $w(hkl) = 1/\sigma^2(|F_{hkl}|)$ or $1/\sigma^2(|F_{hkl}|^2)$, this simplifies to

$$\sigma_i^2 = 1 \bigg/ \left(\sum_3 wg^2\right) = 1/a_{ii}, \tag{18.5.2.10}$$

which is appropriate for absolute weights. Equation (18.5.2.10) provides an s.u. for a parameter relative to the s.u.'s $\sigma(|F|)$ or $\sigma(|F|^2)$ of the observations.

In general, with the full matrix a_{ij} in the normal equations,

$$\sigma_i^2 = (a^{-1})_{ii}, \tag{18.5.2.11}$$

where $(a^{-1})_{ii}$ is an element of the matrix inverse to a_{ij}. The covariance of the parameters u_i and u_j is $\operatorname{cov}(i, j) \equiv \sigma_i\sigma_j\operatorname{correl}(i, j) = (a^{-1})_{ij}$.

18.5.2.2. *Weights*

In the early stages of refinement, artificial weights may be chosen to accelerate refinement. In the final stages, the weights must be related to the precision of the structure factors if parameter variances are being sought. There are two distinct ways, covering two ranges of error, in which this may be done.

(1) The weights for R_1, say, may reflect the precision of the $|F_o|$, so that $w(hkl) = 1/\sigma^2(|F_{hkl}|)$, where σ^2 is the estimated variance of $|F_o|$ due to a specific class of experimental uncertainties. These absolute weights are derived from an analysis of the experiment. Weights chosen in this way lead to estimated parameter variances $\sigma_i^2 = (a^{-1})_{ii}$, (18.5.2.11), which cover only the specific class of experimental uncertainties.

(2) The weights may reflect the trends in the $|\Delta| \equiv \||F_o| - |F_c|\|$. A weighting function with a small number of parameters is chosen so that the averages of $w\Delta^2$ are constant when the set of $w\Delta^2$ values is analysed in any pertinent fashion (*e.g.* in bins of increasing $|F_o|$ and $2\sin\theta/\lambda$). Weights chosen in this way are relative weights, and the expression for the parameter variances needs a scaling factor,

$$S^2 = \left(\sum_3 w\Delta^2\right) \bigg/ (n_{\rm obs} - n_{\rm params}). \tag{18.5.2.12}$$

Hence, in the full-matrix case,

$$\sigma_i^2 = \left[\left(\sum_3 w\Delta^2\right) \bigg/ (n_{\rm obs} - n_{\rm params})\right](a^{-1})_{ii}, \tag{18.5.2.13}$$

which allows for all random experimental errors, such systematic experimental errors as cannot be simulated in the $|F_c|$ and imperfections in the calculated model.

18.5.2.3. Statistical descriptors and goodness of fit

In recent years, there have been developments and changes in statistical nomenclature and usage. Many aspects are summarised in the reports of the IUCr Subcommittee on Statistical Descriptors in Crystallography (Schwarzenbach *et al.*, 1989, 1995). In the second report, *inter alia*, the Subcommittee emphasizes the terms *uncertainty* and *standard uncertainty* (s.u.). The latter is a replacement for the older term *estimated standard deviation* (e.s.d.). The Subcommittee classify uncertainty components in two categories, based on their method of evaluation: type A, estimated by the statistical analysis of a series of observations, and type B, estimated otherwise. As an example of the latter, a type B component could allow for doubts concerning the estimated shape and dimensions of the diffracting crystal and the subsequent corrections made for absorption.

The square root S of the expression S^2, (18.5.2.12) above, is called the *goodness of fit* when the weights are the reciprocals of the absolute variances of the observations.

One recommendation in the second report does call for comment here. While agreeing that formulae like (18.5.2.13) lead to conservative estimates of parameter variances, the report suggests that this practice is based on the questionable assumption that the variances of the observations by which the weights are assigned are relatively correct but uniformly underestimated. When the goodness of fit $S > 1$, then either the weights or the model or both are suspect.

Comment is needed. The account in Section 18.5.2.2 describes two distinct ways of estimating parameter variances, covering two ranges of error. The kind of weights envisaged in the reports (based on variances of type A and/or of type B) are of a class described for method (1). They are not the weights to be used in method (2) (though they may be a component in such weights). Method (2) implicitly assumes from the outset that there are experimental errors, some covered and others not covered by method (1), and that there are imperfections in the calculated model (as is obviously true for proteins). Method (2) avoids exploring the relative proportions and details of these error sources and aims to provide a realistic estimate of parameter uncertainties which can be used in external comparisons. It can be formally objected that method (2) does not conform to the criteria of random-variable theory, since clearly the Δ's are partially correlated through the remaining model errors and some systematic experimental errors. But it is a useful procedure. Method (1) on its own would present an optimistic view of the reliability of the overall investigation, the degree of optimism being indicated by the inverse of the goodness of fit (18.5.2.12). In method (2), if the weights are on an arbitrary scale, then S^2 can have an arbitrary value.

For an advanced-level treatment of many aspects of the refinement of structural parameters, see Part 8 of *International Tables for Crystallography*, Volume C (2004). The detection and treatment of systematic error are discussed in Chapter 8.5 therein.

18.5.3. Restrained refinement

18.5.3.1. Residual function

Protein structures are often refined by a restrained refinement program such as *PROLSQ* (Hendrickson & Konnert, 1980). Here, a function of the type

$$R' = \sum w_h(\Delta F)^2 + \sum w_{\rm geom}(\Delta Q)^2 \qquad (18.5.3.1)$$

is minimized, where Q denotes a geometrical restraint such as a bond length. Formally, all one is doing is extending the list of observations. One is adding to the protein diffraction data geometrical data from a stereochemical dictionary such as that of Engh & Huber (1991). A chain C—N bond length may be known from the dictionary with much greater precision $1/w_{\rm geom}^{1/2}$, say 0.02 Å, than from an unrestrained diffraction-data-only protein refinement.

In a high-resolution unrestrained refinement of a small molecule, the standard uncertainty (s.u.) of a bond length $A-B$ is often well approximated by

$$\sigma(l) = (\sigma_A^2 + \sigma_B^2)^{1/2}. \qquad (18.5.3.2)$$

However, in a protein determination $\sigma(l)$ is often much smaller than either σ_A or σ_B because of the excellent information from the stereochemical dictionary, which correlates the positions of A and B.

Laying aside computational size and complexity, the protein precision problem is straightforward in principle. When a restrained refinement has converged to an acceptable structure and the shifts in successive rounds have become negligible, invert the full matrix. The inverse matrix immediately yields estimates of the variances and covariances of all parameters.

The dimensions of the matrix are the same whether or not the refinement is restrained. The full matrix will be rather sparse, but not nearly as sparse as in a small-molecule refinement. For the purposes of Section 18.5.3, it is irrelevant whether the residual for the diffraction data is based on $|F|$ or $|F|^2$. On the relative weighting of the diffraction and restraint terms, see Section 18.5.3.3.

18.5.3.2. A very simple protein model

Some aspects of restrained refinement are easily understood by considering a *one-dimensional protein consisting of two like atoms* in the asymmetric unit, with coordinates x_1 and x_2 relative to a fixed origin and bond length $l = x_2 - x_1$. In the refinement, the normal equations are of the type $\mathbf{N}\Delta\mathbf{x} = \mathbf{e}$. For two non-overlapping like atoms, the *diffraction data* will yield a normal matrix

$$\mathbf{N} = \begin{pmatrix} a & 0 \\ 0 & a \end{pmatrix}, \qquad (18.5.3.3)$$

with inverse

$$\begin{pmatrix} 1/a & 0 \\ 0 & 1/a \end{pmatrix}, \qquad (18.5.3.4)$$

where

$$a = \sum w_h(\partial|F_n|/\partial x_i)^2. \qquad (18.5.3.5)$$

A *geometric restraint* on the length will yield a normal matrix

$$\begin{pmatrix} b & -b \\ -b & b \end{pmatrix} \qquad (18.5.3.6)$$

with no inverse, since its determinant is zero, where

$$b = w_{\rm geom}(\partial l/\partial x_i)^2. \qquad (18.5.3.7)$$

Note $\partial l/\partial x_2 = -\partial l/\partial x_i = 1$, so that

$$b = w_{\rm geom} = 1/\sigma_{\rm geom}^2(l), \qquad (18.5.3.8)$$

where $\sigma^2_{\rm geom}(l)$ is the variance assigned to the length in the stereochemical dictionary.

Combining the diffraction data and the restraint, the normal matrix becomes

$$\begin{pmatrix} a+b & -b \\ -b & a+b \end{pmatrix}, \tag{18.5.3.9}$$

with inverse

$$\{1/[a(a+2b)]\}\begin{pmatrix} a+b & b \\ b & a+b \end{pmatrix}. \tag{18.5.3.10}$$

For the diffraction data alone, the variance of x_i is

$$\sigma^2_{\rm diff}(x_i) = 1/a. \tag{18.5.3.11}$$

For the diffraction data plus restraint, the variance of x_i is

$$\begin{aligned}\sigma^2_{\rm res}(x_i) &= (a+b)/[a(a+2b)]\\ &< \sigma^2_{\rm diff}(x_i).\end{aligned} \tag{18.5.3.12}$$

Note that though the restraint says nothing about the position of x_i, the variance of x_i has been reduced because of the coupling to the position of the other atom. In the limit when $a \ll b$, $\sigma^2_{\rm res}(x_i)$ is only half $\sigma^2_{\rm diff}(x_i)$.

The general formula for the variance of the length $l = x_2 - x_1$ is

$$\sigma^2(l) = \sigma^2(x_2) - 2{\rm cov}(x_2, x_1) + \sigma^2(x_1). \tag{18.5.3.13}$$

For the diffraction data alone, this gives

$$\sigma^2_{\rm diff}(l) = 1/a + 0 + 1/a = 2/a = 2\sigma^2_{\rm diff}(x_i), \tag{18.5.3.14}$$

as expected. For the diffraction data plus restraint,

$$\begin{aligned}\sigma^2_{\rm res}(l) &= [1/a(a+2b)][(a+b) - 2b + (a+b)]\\ &= 1/(a/2+b)\\ &< \sigma^2_{\rm diff}(l).\end{aligned} \tag{18.5.3.15}$$

For small a, $\sigma^2_{\rm res}(l) \to 1/b = \sigma^2_{\rm geom}(l)$, as expected. The variance of the restrained length, (18.5.3.15), can be re-expressed as

$$1/\sigma^2_{\rm res}(l) = 1/\sigma^2_{\rm diff}(l) + 1/\sigma^2_{\rm geom}(l). \tag{18.5.3.16}$$

For the two-atom protein, it can be proved directly, as one would expect from (18.5.3.16), that *restrained refinement determines a length which is the weighted mean of the diffraction-only length and the geometric dictionary length.*

The centroid has coordinate $c = (x_1 + x_2)/2$. It is easily found that $\sigma^2_{\rm res}(c) = \sigma^2_{\rm diff}(c) = 1/2a$. Thus, as expected, the restraint says nothing about the position of the molecule in the cell.

For numerical illustrations of the s.u.'s in restrained refinement, suppose the stereochemical length restraint has $\sigma_{\rm geom}(l) = 0.02$ Å. Equation (18.5.3.16) gives the length s.u. $\sigma_{\rm res}(l)$ in restrained refinement. If the diffraction-only $\sigma_{\rm diff}(x_i) = 0.01$ Å, the restrained $\sigma_{\rm res}(l)$ is 0.012 Å. If $\sigma_{\rm diff}(x_i) = 0.05$ Å, $\sigma_{\rm res}(l)$ is 0.019 Å. However large $\sigma_{\rm diff}(x_i)$, $\sigma_{\rm res}(l)$ never exceeds 0.02 Å.

Equation (18.5.3.12) gives the position s.u. $\sigma_{\rm res}(x_i)$ in restrained refinement. If the diffraction-only $\sigma_{\rm diff}(x_i) = 0.01$ Å, the restrained $\sigma_{\rm res}(x_i)$ is 0.009 Å. If $\sigma_{\rm diff}(x_i) = 0.05$ Å, $\sigma_{\rm res}(x_i) = 0.037$ Å. For large $\sigma_{\rm diff}(x_i)$, $\sigma_{\rm res}(x_i)$ tends to $\sigma_{\rm diff}(x_i)/(2)^{1/2}$ as the strong restraint couples the two atoms together. For very small $\sigma_{\rm diff}(x_i)$, the relatively weak restraint has no effect.

18.5.3.3. *Relative weighting of diffraction and restraint terms*

When only relative diffraction weights are known, as in equation (18.5.2.13), it has been common (Rollett, 1970) to scale the geometric restraint terms against the diffraction terms by replacing the restraint weights $w_{\rm geom} = 1/\sigma^2_{\rm geom}$ by $w_{\rm geom} = S^2/\sigma^2_{\rm geom}$, where $S^2 = (\sum w_h \Delta_h^2)/(n_{\rm obs} - n_{\rm params})$. However, this scheme cannot be used for low-resolution structures if $n_{\rm obs} < n_{\rm params}$.

The treatment by Tickle *et al.* (1998*a*) shows that the reduction $n_{\rm params}$ in the number of degrees of freedom has to be distributed among all the data, both diffraction observations and restraints. Since the geometric restraint weights are on an absolute scale (Å^{-2}), they propose that the (absolute) scale of the diffraction weights should be determined by adjustment until the restrained residual R' (18.5.3.1) is equal to its expected value ($n_{\rm obs} + n_{\rm restraints} - n_{\rm params}$).

For a method of determining the scale of the diffraction weights based on $R_{\rm free}$, see Brünger (1993).

The geometric restraint weights were classified by the IUCr Subcommittee (Schwarzenbach *et al.*, 1995) as derived from observations supplementary to the diffraction data, with uncertainties of type B (Section 18.5.2.3).

18.5.4. Two examples of full-matrix inversion

18.5.4.1. *Unrestrained and restrained inversions for concanavalin A*

G. M. Sheldrick extended his *SHELXL*96 program (Sheldrick & Schneider, 1997) to provide extra information about protein precision through the inversion of least-squares full matrices. His programs have been used by Deacon *et al.* (1997) for the high-resolution refinement of native concanavalin A with 237 residues, using data at 110 K to 0.94 Å refined anisotropically. After the convergence and completion of full-matrix restrained refinement for the structure, the unrestrained full matrix (coordinates only) was computed and then inverted in a massive calculation. This led to s.u.'s $\sigma(x)$, $\sigma(y)$, $\sigma(z)$ and $\sigma(r)$ for all atoms, and to $\sigma(l)$ and $\sigma(\theta)$ for all bond lengths and angles. $\sigma(r)$ is defined as $[\sigma^2(x) + \sigma^2(y) + \sigma^2(z)]^{1/2}$. For concanavalin A the restrained full matrix was also inverted, thus allowing the comparison of restrained and unrestrained s.u.'s.

The results for concanavalin A from the inversion of the coordinate matrices of order 6402 (= 2134 × 3) are plotted in Figs. 18.5.4.1 and 18.5.4.2. Fig. 18.5.4.1 shows $\sigma(r)$ *versus* $B_{\rm eq}$ for the fully occupied atoms of the protein (a few atoms with $B >$ 60 Å^2 are off-scale). The points are colour-coded black for carbon, blue for nitrogen and red for oxygen. Fig. 18.5.4.1(*a*) shows the restrained results, and Fig. 18.5.4.1(*b*) shows the unrestrained diffraction-data-only results. Superposed on both sets of data points are least-squares quadratic fits determined with weights $1/B^2$. At high B, the unrestrained $\sigma_{\rm diff}(r)$ can be at least double the restrained $\sigma_{\rm res}(r)$, *e.g.*, for carbon at B = 50 Å^2, the unrestrained $\sigma_{\rm diff}(r)$ is about 0.25 Å, whereas the restrained $\sigma_{\rm res}(r)$ is about 0.11 Å. For B < 10 Å^2, both $\sigma(r)$'s fall below 0.02 Å and are around 0.01 Å at B = 6 Å^2.

For B < 10 Å^2, the better precision of oxygen as compared with nitrogen, and of nitrogen as compared with carbon, can be clearly seen. At the lowest B, the unrestrained $\sigma_{\rm diff}(r)$ in Fig. 18.5.4.1(*b*) are almost as small as the restrained $\sigma_{\rm res}(r)$ in Fig. 18.5.4.1(*a*). [The quadratic fits of the restrained results in Fig. 18.5.4.1(*a*) are evidently slightly imperfect in making $\sigma_{\rm res}(r)$ tend almost to 0 as B tends to 0.]

Fig. 18.5.4.2 shows $\sigma(l)$ *versus* $B_{\rm eq}$ for the bond lengths in the protein. The points are colour-coded black for C—C, blue for C—N and red for C—O. The restrained and unrestrained distributions are very different for high B. The restrained distribution in

(*b*)

Figure 18.5.4.2
Plots of $\sigma(l)$ *versus* average $B_{\rm eq}$ for concanavalin A with 0.94 Å data, (*a*) restrained full-matrix $\sigma_{\rm res}(l)$, (*b*) unrestrained full-matrix $\sigma_{\rm diff}(l)$. C—C black, C—N blue, C—O red.

Fig. 18.5.4.2(*a*) tends to about 0.02 Å, which is the standard uncertainty of the applied restraint for 1–2 bond lengths, whereas the unrestrained distribution in Fig. 18.5.4.2(*b*) goes off the scale of the diagram. But for $B < 10$ Å^2, both distributions fall to around 0.01 Å.

The differences between the restrained and unrestrained $\sigma(r)$ and $\sigma(l)$ can be understood through the two-atom model for restrained refinement described in Section 18.5.3. For that model, the equation

$$1/\sigma^2_{\rm res}(l) = 1/\sigma^2_{\rm diff}(l) + 1/\sigma^2_{\rm geom}(l) \qquad (18.5.3.16)$$

relates the bond-length s.u. in the restrained refinement, $\sigma_{\rm res}(l)$, to the $\sigma_{\rm diff}(l)$ of the unrestrained refinement and the s.u. $\sigma_{\rm geom}(l)$ assigned to the length in the stereochemical dictionary. In the refinements, $\sigma_{\rm geom}(l)$ was 0.02 Å for all bond lengths. When this is combined in (18.5.3.16) with the unrestrained $\sigma_{\rm diff}(l)$ of any bond, the predicted restrained $\sigma_{\rm res}(l)$ is close to that found in the restrained full matrix.

It can be seen from Fig. 18.5.4.2(*b*) that many bond lengths with average $B < 10$ Å^2 have $\sigma_{\rm diff}(l) < 0.014$ Å. For these bonds the diffraction data have greater weight than the stereochemical dictionary. Some bonds have $\sigma_{\rm diff}(l)$ as low as 0.0080 Å, with $\sigma_{\rm res}(l)$ around 0.0074 Å. This situation is one consequence of the availability of diffraction data to the high resolution of 0.94 Å. For large $\sigma_{\rm diff}(l)$ (*i.e.*, high B), equation (18.5.3.16)

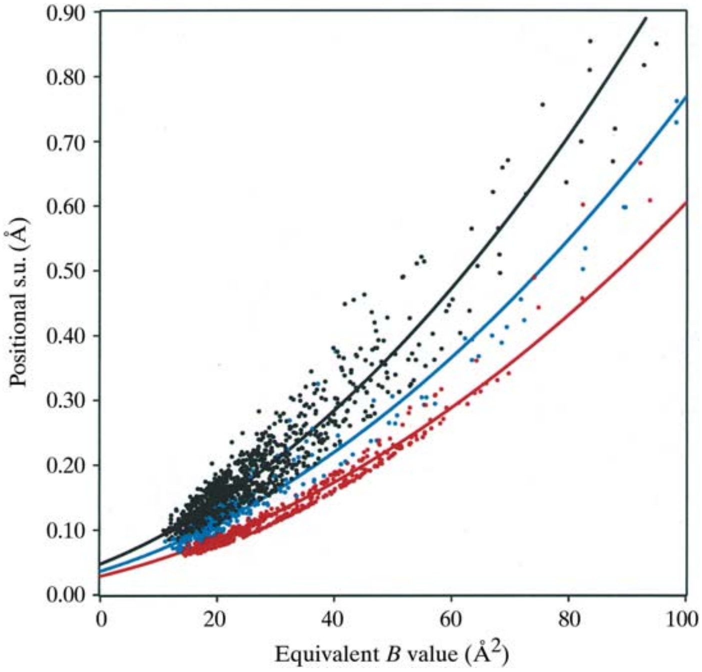

Figure 18.5.4.3
Plot of $\sigma_{\rm diff}(r)$ *versus* $B_{\rm eq}$ from an unrestrained full matrix for immunoglobulin mutant (T39K) with 1.70 Å data. Carbon black, nitrogen blue, oxygen red.

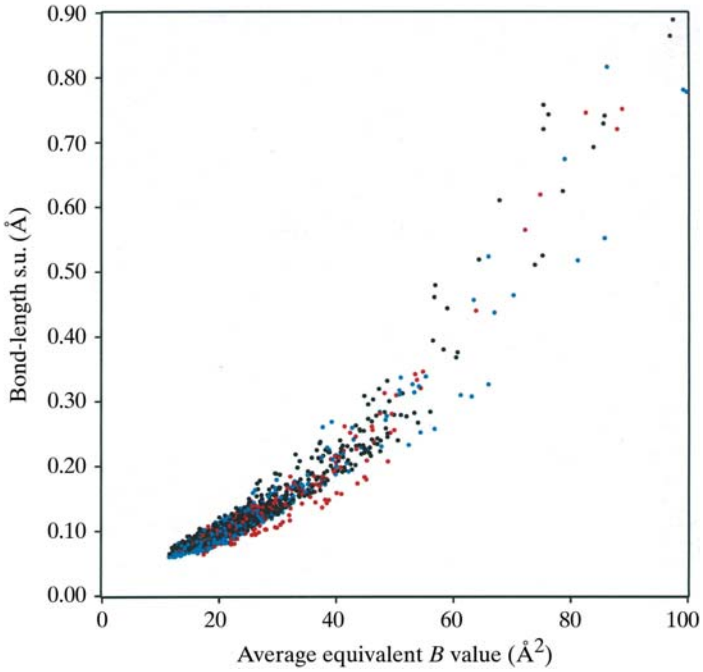

Figure 18.5.4.4
Plot of $\sigma_{\rm diff}(l)$ *versus* average $B_{\rm eq}$ from an unrestrained full matrix for immunoglobulin mutant (T39K) with 1.70 Å data. C—O black, C—N blue, C—O red.

predicts that $\sigma_{\rm res}(l) = \sigma_{\rm geom}(l) = 0.02$ Å, as is found in Fig. 18.5.4.2(*a*).

In an isotropic approximation, $\sigma(r) = 3^{1/2}\sigma(x)$. Equation (18.5.3.12) of the two-atom model can be recast to give

$$\sigma^2_{\rm res}(r) = \sigma^2_{\rm diff}(r)\left\{\left[\sigma^2_{\rm diff}(r) + 3(0.02)^2\right]\Big/\left[2\sigma^2_{\rm diff}(r) + 3(0.02)^2\right]\right\}. \qquad (18.5.4.1)$$

For low B, say $B \leq 15$ Å^2 in concanavalin, (18.5.4.1) gives quite good predictions of $\sigma_{\rm res}(r)$ from $\sigma_{\rm diff}(r)$. For instance, for a carbon atom with B = 15 Å^2, the quadratic curve for carbon in Fig. 18.5.4.1(*b*) shows $\sigma_{\rm diff}(r) = 0.034$ Å, and Fig. 18.5.4.1(*a*) shows $\sigma_{\rm res}(r) = 0.029$ Å. While if $\sigma_{\rm diff}(r) = 0.034$ Å is used with (18.5.4.1), the resulting prediction for $\sigma_{\rm res}(r)$ is 0.028 Å.

However, for high B, say B = 50 Å^2, the quadratic curve for carbon in Fig. 18.5.4.1(*b*) shows $\sigma_{\rm diff}(r) = 0.25$ Å, and Fig. 18.5.4.1(*a*) shows $\sigma_{\rm res}(r) = 0.11$ Å, whereas (18.5.4.1) leads to the poor estimate $\sigma_{\rm res}(r) = 0.18$ Å.

Thus at high B, equation (18.5.4.1) from the two-atom model does not give a good description of the relationship between the restrained and unrestrained $\sigma(r)$. The reason is obvious. Most atoms are linked by 1–2 bond restraints to two or three other atoms. Even a carbonyl oxygen atom linked to its carbon atom by a 0.02 Å restraint is also subject to 0.04 Å 1–3 restraints to chain C_α and N atoms. Consequently, for a high-B atom, when the restraints are applied it is coupled to several other atoms in a group, and its $\sigma_{\rm res}(r)$ is lower, compared with the diffraction-data-only $\sigma_{\rm diff}(r)$, by a greater amount than would be expected from the two-atom model.

18.5.4.2. *Unrestrained inversion for an immunoglobulin*

Sheldrick has provided the results of the unrestrained lower-resolution refinement of a single-chain immunoglobulin mutant (T39K) with 218 amino-acid residues, with data to 1.70 Å refined isotropically (Usón *et al.*, 1999). Fig. 18.5.4.3 shows $\sigma_{\rm diff}(r)$ *versus* $B_{\rm eq}$ for the fully occupied protein atoms. Superposed on the data points are least-squares quadratic fits. In a first very rough approximation for $\sigma_{\rm diff}(x_i)$ suggested later by equation (18.5.6.3), the dependence on atom type is controlled by $1/Z_i$, the reciprocal of the atomic number. Sheldrick found that a $1/Z_i$ dependence produced too little difference between C, N and O. The proportionalities between the quadratics for $\sigma(r)$ in Figs. 18.5.4.1 and 18.5.4.3 are based on the reciprocals of the scattering factors at $\sin\theta/\lambda = 0.3$ Å^{-1}, symbolized by $Z^\#_i$. For C, N and O, these are 2.494, 3.219 and 4.089, respectively. For potential use in later work, the least-squares fits to the $\sigma(r_i)Z^\#_i$ in Å are recorded here as

$$0.11892 + 0.00891B + 0.0001462B^2, \qquad (18.5.4.2a)$$

$$0.01826 + 0.001043B + 0.0002230B^2 \text{ and} \qquad (18.5.4.2b)$$

$$0.00115 + 0.004414B + 0.0000214B^2 \qquad (18.5.4.2c)$$

for the immunoglobulin (unrestrained), concanavalin A (unrestrained) and concanavalin A (restrained), respectively.

As might be expected from the lower resolution, the lowest $\sigma_{\rm diff}(r)$'s in the immunoglobulin are about six times the lowest $\sigma_{\rm diff}(r)$'s in concanavalin. But at B = 50 Å^2, the immunoglobulin curve for carbon gives $\sigma_{\rm diff}(r) = 0.37$ Å, which is only 50% larger than the concanavalin value of 0.25 Å.

Fig. 18.5.4.4 shows $\sigma_{\rm diff}(l)$ *versus* $B_{\rm eq}$ for the immunoglobulin. Note that the lowest immunoglobulin unrestrained $\sigma_{\rm diff}(l)$ is about 0.06 Å, which is three times the 0.02 Å $\sigma_{\rm geom}(l)$ bond restraint.

18.5.4.3. *Comments on restrained refinement*

Geometric restraint dictionaries typically use bond-length weights based on $\sigma_{\rm geom}(l)$ of around 0.02 or 0.03 Å. Tables 18.5.7.1–18.5.7.3 show that even 1.5 Å studies have diffraction-only errors $\sigma_{\rm diff}(x, B_{\rm avg})$ of 0.08 Å and upwards. Only for resolutions of 1.0 Å or so are the diffraction-only errors comparable with the dictionary weights. Of course, the dictionary offers no values for many of the configurational parameters of the protein structure, including the centroid and molecular orientation.

18.5.4.4. Full-matrix estimates of precision

The opening contention of this chapter in Section 18.5.1.1 is that the variances and covariances of the structural parameters of proteins can be found from the inverse of the least-squares normal matrix. But there is a caveat, chiefly that explicit account would not be taken of disorder of the solvent or of parts of the protein. Corrections by Babinet's principle of complementarity or by mask bulk solvent models are only first-order approximations. The consequences of such disorder problems, which make the variation of calculated structure factors nonlinear over the range of interest, may in future be better handled by maximum-likelihood methods (*e.g.* Read, 1990; Bricogne, 1993; Bricogne & Irwin, 1996; Murshudov *et al.*, 1997). Pannu & Read (1996) have shown how the maximum-likelihood method can be cast computationally into a form akin to least-squares calculations. Full-matrix precision estimates along the lines of the present chapter are probably somewhat low.

It should also be noted that full-matrix estimates of coordinate precision are most reliably derived from matrices involving both coordinates and atomic displacement parameters. This is particularly important for lower-resolution analyses, in which atomic images overlap. The work on the high-resolution analysis of concanavalin A described in Section 18.5.4.1 was based on the very large coordinate matrix, of order 6402. The omission, because of computer limitations, of the anisotropic displacement parameters from the full matrix will have caused the coordinate s.u.'s of atoms with high $B_{\rm eq}$ to be underestimated.

Much information about the quality of a molecular model can be obtained from the eigenvalues and eigenvectors of the normal matrix (Cowtan & Ten Eyck, 2000).

18.5.5. Approximate methods

18.5.5.1. Block calculations

The full-matrix inversions described in the previous section require massive calculations. The length of the calculations is more a matter of the order of the matrix, *i.e.*, the number of parameters, than of the number of observations. When restraints are applied, it is the diffraction-cum-restraints full matrix which should be inverted.

With the increasing power of computers and more efficient algorithms (*e.g.* Tronrud, 1999; Murshudov *et al.*, 1999), a final full matrix should be computed and inverted much more regularly – and not just for high-resolution analyses. Low-resolution analyses have a need, beyond the indications given by B values, to identify through $\sigma(x)$ estimates their regions of tolerable and less tolerable precision.

If full-matrix calculations are impractical, partial schemes can be suggested. As far back as 1973, Watenpaugh *et al.* (1973), in a study of rubredoxin at 1.5 Å resolution, effectively inverted the diffraction full matrix in 200 parameter blocks to obtain individual s.u.'s. A similar scheme for restrained refinements could also use overlapping large blocks. A minimal block scheme in refinements of any resolution is to calculate blocks for each residue and for the block interactions between successive residues. The inversion process could then use the matrices in running groups of three successive residues, taking only the inverted elements for the central residue as the estimates of its variances and covariances.

For low-resolution analyses with very large numbers of atoms, it might be sufficient to gain a general idea of the behaviour of $\sigma(x)$ as a function of B by computing a limited number of blocks for representative or critical groups of residues. The parameters used in the blocks should include the B's, since atomic images overlap at low resolution, thus correlating the position of one atom with the displacement parameters of its neighbours.

18.5.5.2. The modified Fourier method

In the simplest form of the Fourier-map approach to centrosymmetric high-resolution structures, atomic positions are given by the maxima of the observed electron density. The uncertainty of such a position may be estimated as the uncertainty in the slope function (first derivative) divided by the curvature (second derivative) at the peak (Cruickshank, 1949*a*), *i.e.*,

$$\sigma(x) = \sigma(\text{slope})/(\text{atomic peak `curvature'}). \qquad (18.5.5.1)$$

However, atomic positions are affected by finite-series and peak-overlapping effects.

Hence, more generally, atomic positions may be determined by the requirement that the slope of the difference map at the position of atom r should be zero, or equivalently that the slopes at atom r of the observed and calculated electron densities should be equal. As a criterion this becomes the basis of the modified Fourier method (Cruickshank, 1952, 1959, 1999; Bricogne, 2008, Section 1.3.4.4.7.5), which, like the least-squares method, is applicable whether or not the atomic peaks are resolved and is applicable to noncentrosymmetric structures. For refinement, a set of n simultaneous linear equations are involved, analogous to the normal equations of least squares. Their right-hand sides are the slopes of the difference map at the trial atomic positions.

The diagonal elements of the matrix, for coordinate x_r of an atom with Debye B value B_r, are approximately equal to

$$\text{`curvature'} = (4\pi^2/a^2V)\left[\sum_{hkl}(m/2)h^2 f_r \exp(-B_r \sin^2\theta/\lambda^2)\right], \qquad (18.5.5.2)$$

where $m = 1$ or 2 for acentric or centric reflections. The summation is over all independent planes and their symmetry equivalents. Strictly speaking, (18.5.5.2) is a curvature only for centrosymmetric structures.

In the modified Fourier method,

$$\sigma(\text{slope}) = (2\pi/aV)\left[\sum_{hkl} h^2(\Delta|F|^2)\right]^{1/2}. \qquad (18.5.5.3)$$

This is simply an estimate of the r.m.s. uncertainty at a general position (Cruickshank & Rollett, 1953) in the slope of the difference map, *i.e.*, the r.m.s. uncertainty on the right-hand side of the modified Fourier method.

$\sigma(x)$ is then given by (18.5.5.1), using (18.5.5.3) and (18.5.5.2).

18.5.5.3. Application of the modified Fourier method

An extreme example of an apparently successful gross approximation to protein precision is represented by Daopin *et al.*'s (1994) treatment of two independent determinations (at 1.8 and 1.95 Å) of the structure of TGF-β2. They reported that the modified Fourier-map formulae given in Section 18.5.5.2 yielded a quite good description of the B dependence of the positional differences between the two independent determinations. However, there is a formal difficulty about this application. Equation (18.5.5.1) derives from a diffraction-data-only approach, whereas the two structures were determined from restrained refinements. Even though the *TNT* restraint parameters and weights may have been the same in both refinements, it is slightly surprising that (18.5.5.1) should have worked well.

Equation (18.5.2.1) requires the summation of various series over all (*hkl*) observations; such calculations are not customarily provided in protein programs. However, due to the fundamental similarities between Fourier and least-squares methods demonstrated by Cochran (1948), Cruickshank (1949*b*, 1952, 1959), and Cruickshank & Robertson (1953), closely similar estimates of the precision of individual atoms can be obtained from the reciprocal of the diagonal elements of the diffraction-data-only least-squares matrix. These elements will often have been calculated already within the protein refinement programs, but possibly never output. Such estimates could be routinely available.

Between approximations using largish blocks and those using only the reciprocals of diagonal terms, a whole variety of intermediate approximations involving some off-diagonal terms could be envisaged.

Whatever method is used to estimate uncertainties, it is essential to distinguish between *coordinate* uncertainty, *e.g.*, $\sigma(x)$, and *position* uncertainty $\sigma(r) = [\sigma^2(x) + \sigma^2(y) + \sigma^2(z)]^{1/2}$.

The remainder of this chapter discusses two rough-and-ready indicators of structure precision: the diffraction-component precision index (DPI) and Luzzati plots.

18.5.6. The diffraction-component precision index

18.5.6.1. Statistical expectation of error dependence

From general statistical theory, one would expect the s.u. of an atomic coordinate determined from the diffraction data alone to show dependence on four factors:

$$\sigma(x) \propto (\mathcal{R})\big[(n_{\rm atoms})/(n_{\rm obs} - n_{\rm params})\big]^{1/2}(1/s_{\rm rms}). \qquad (18.5.6.1)$$

Here, $\mathcal{R}$ is some measure of the precision of the data; $n_{\rm atoms}$ is the recognition that the information content of the data has to be shared out; $n_{\rm obs}$ is the number of independent data, but to achieve the correct number of degrees of freedom this must be reduced by $n_{\rm params}$, the number of parameters determined; and $1/s_{\rm rms}$ is a more specialized factor arising from the sensitivity $\partial|F|/\partial x$ of the data to the parameter x. Here $s_{\rm rms}$ is the r.m.s. reciprocal radius of the data. Any statistical error estimate must show some correspondence to these four factors.

18.5.6.2. A simple error formula

Cruickshank (1960) offered a simple order-of-magnitude formula for $\sigma(x)$ in small molecules. It was intended for use in experimental design: how many data of what precision are needed to achieve a given precision in the results? The formula, derived from a very rough estimate of a least-squares diagonal element in non-centrosymmetric space groups, was

$$\sigma(x_i) = (1/2)(N_i/p)^{1/2}[R/s_{\rm rms}]. \qquad (18.5.6.2)$$

Here $p = n_{\rm obs} - n_{\rm params}$, R is the usual residual $\sum|\Delta F|/\sum|F|$ and N_i is the number of atoms of type i needed to give scattering power at $s_{\rm rms}$ equal to that of the asymmetric unit of the structure, *i.e.*, $\sum_j f_j^2 \equiv N_i f_i^2$. [The formula has also proved very useful in a systematic study of coordinate precision in the many thousands of small-molecule structure analyses recorded in the Cambridge Structural Database (Allen *et al.*, 1995*a*,*b*).]

For small molecules, the above definition of N_i allowed the treatment of different types of atom with not-too-different B's. However, it is not suitable for individual atoms in proteins where there is a very large range of B values and some atoms have B's so large as to possess negligible scattering power at $s_{\rm rms}$.

Often, as in isotropic refinement, $n_{\rm params} \simeq 4n_{\rm atoms}$, where $n_{\rm atoms}$ is the total number of atoms in the asymmetric unit. For fully anisotropic refinement, $n_{\rm params} \simeq 9n_{\rm atoms}$.

A first very rough extension of (18.5.6.2) for application in proteins to an atom with $B = B_i$ is

$$\sigma(x_i) = k(N_i/p)^{1/2}\big[g(B_i)/g(B_{\rm avg})\big]C^{-1/3}Rd_{\rm min}, \qquad (18.5.6.3)$$

where k is about 1.0, $N_i = \sum Z_j^2/Z_i^2$, $B_{\rm avg}$ is the average B for fully occupied sites and C is the fractional completeness of the data to $d_{\rm min}$. In deriving (18.5.6.3) from (18.5.6.2), $1/s_{\rm rms}$ has been replaced by $1.3d_{\rm min}$, and the factor $(1/2)(1.3) = 0.65$ has been increased to 1.0 as a measure of caution in the replacement of a full matrix by a diagonal approximation. $g(B) = 1 + a_1B + a_2B^2$ is an empirical function to allow for the dependence of $\sigma(x)$ on B. However, the results in Section 18.5.4.2 showed that the parameters a_1 and a_2 depend on the structure.

As also mentioned in Section 18.5.4.2, Sheldrick has found that the Z_i in N_i is better replaced by $Z_i^{\#}$, the scattering factor at $\sin\theta/\lambda = 0.3$ Å^{-1}. Hence, N_i may be taken as

$$N_i = (\textstyle\sum Z_j^{\#2}/Z_i^{\#2}). \qquad (18.5.6.4)$$

A useful comparison of the relative precision of different structures may be obtained by comparing atoms with the respective $B = B_{\rm avg}$ in the different structures. (18.5.6.3) then reduces to

$$\sigma(x, B_{\rm avg}) = 1.0(N_i/p)^{1/2}C^{-1/3}Rd_{\rm min}. \qquad (18.5.6.5)$$

The smaller the $d_{\rm min}$ and the R, the better the precision of the structure. If the difference between oxygen, nitrogen and carbon atoms is ignored, N_i may be taken simply as the number of fully occupied sites. For heavy atoms, (18.5.6.4) must be used for N_i.

Equation (18.5.6.5) is not to be regarded as having absolute validity. It is a quick and rough guide for the diffraction-data-only error component for an atom with Debye B equal to the $B_{\rm avg}$ for the structure. It is named the *diffraction-component precision index*, or DPI. It contains none of the restraint data.

18.5.6.3. Extension for low-resolution structures and use of R_{free}

For low-resolution structures, the number of parameters may exceed the number of diffraction data. In (18.5.6.3) and (18.5.6.5), $p = n_{\rm obs} - n_{\rm params}$ is then negative, so that $\sigma(x)$ is imaginary. This difficulty can be circumvented *empirically* by replacing p with $n_{\rm obs}$ and R with $R_{\rm free}$ (Brünger, 1992). The counterpart of the DPI (18.5.6.5) is then

$$\sigma(x, B_{\rm avg}) = 1.0(N_i/n_{\rm obs})^{1/2}C^{-1/3}R_{\rm free}d_{\rm min}. \qquad (18.5.6.6)$$

Here $n_{\rm obs}$ is the number of reflections included in the refinement, not the number in the $R_{\rm free}$ set.

It may be asked: how can there be any estimate for the precision of a coordinate from the diffraction data only when there are insufficient diffraction data to determine the structure? By following the line of argument of Cruickshank's (1960) analysis, (18.5.6.6) is a rough estimate of the square root of the reciprocal of one diagonal element of the diffraction-only least-squares matrix. All the other parameters can be regarded as having been determined from a diffraction-plus-restraints matrix.

Clearly, (18.5.6.6) can also be used as a general alternative to (18.5.6.5) as a DPI, irrespective of whether the number of degrees of freedom $p = n_{\rm obs} - n_{\rm params}$ is positive or negative.

Table 18.5.7.1
Comparison of full-matrix $\sigma(r, B_{\rm avg})$ with the diffraction-component precision index (DPI)

Protein	$(N_i/p)^{1/2}$	R	$d_{\min}$ (Å)	DPI $\sigma(r, B_{\rm avg})$ (Å)	Full-matrix $\sigma_{\rm diff}(r, B_{\rm avg})$ (Å)	Reference
Concanavalin A	0.148	0.128	0.94	0.034	0.033	(*a*)
Immunoglobulin	0.476	0.156	1.70	0.221	0.186	(*b*)

References: (*a*) Deacon *et al.* (1997); (*b*) Usón *et al.* (1999).

Comment. When p is positive, (18.5.6.6) would be exactly equivalent to (18.5.6.5) only if $R_{\rm free} = R[n_{\rm obs}/(n_{\rm obs} - n_{\rm params})]^{1/2}$. Tickle *et al.* (1998*b*) have shown that the expected relationship in a restrained refinement is actually

$$R_{\rm free} = R\{[n_{\rm obs} + (n_{\rm params} - h)]/[n_{\rm obs} - (n_{\rm params} - h)]\}^{1/2}, \qquad (18.5.6.7)$$

where $h = n_{\rm restraints} - \sum w_{\rm geom}(\Delta Q)^2$, the latter term, as in (18.5.3.1), being the weighted sum of the squares of the restraint residuals.

18.5.6.4. Position error

Often an estimate of a position error $|\Delta \mathbf{r}|$, rather than a coordinate error $|\Delta x|$, is required. In the isotropic approximation,

$$\sigma(r, B_{\rm avg}) = 3^{1/2}\sigma(x, B_{\rm avg}). \qquad (18.5.6.8)$$

Consequently, the DPI formulae for the position errors are

$$\sigma(r, B_{\rm avg}) = 3^{1/2}(N_i/p)^{1/2}C^{-1/3}Rd_{\min} \qquad (18.5.6.9)$$

with R and

$$\sigma(r, B_{\rm avg}) = 3^{1/2}(N_i/n_{\rm obs})^{1/2}C^{-1/3}R_{\rm free}d_{\min} \qquad (18.5.6.10)$$

with $R_{\rm free}$.

18.5.7. Examples of the diffraction-component precision index

18.5.7.1. Full-matrix comparison with the diffraction-component precision index

The DPI (18.5.6.9) with R was offered as a quick and rough guide for the diffraction-data-only error for an atom with $B = B_{\rm avg}$. The necessary data for the comparison with the two unrestrained full-matrix inversions of Section 18.5.5 are given in Table 18.5.7.1. For concanavalin A with $B_{\rm avg} = 14.8$ Å^2, the full-matrix quadratic (18.5.4.2*b*) gives 0.033 Å for a carbon atom and the DPI gives 0.034 Å for an unspecified atom. For the immunoglobulin with $B_{\rm avg} = 26.8$ Å^2, the full-matrix quadratic (18.5.4.2*a*) gives $\sigma_{\rm diff}(r) = 0.19$ Å for a carbon atom, while the DPI gives 0.22 Å.

For these two structures, the simple DPI formula compares surprisingly well with the unrestrained full-matrix calculations at $B_{\rm avg}$.

For the restrained full-matrix calculations on concanavalin A, the quadratic (18.5.4.2*c*) with $B = B_{\rm avg}$ gives $\sigma_{\rm res}(r) = 0.028$ Å for a carbon atom, which is only 15% smaller than the unrestrained 0.033 Å. This small decrease matches the discussion of $\sigma_{\rm res}(r)$ and $\sigma_{\rm diff}(r)$ in Section 18.5.4.1 following equation (18.5.4.1). But that discussion also indicates that for the immunoglobulin, the restrained $\sigma_{\rm res}(r, B_{\rm avg})$, which was not computed, will be proportionaly much lower than the unrestrained value of $\sigma_{\rm diff}(r, B_{\rm avg}) = 0.19$ Å, since the restraints are relatively more important in the immunoglobulin.

18.5.7.2. Further examples of the DPI using R

Table 18.5.7.2 shows a range of examples of the application of the DPI (18.5.6.9) using R to proteins of differing precision, starting with the smallest $d_{\min}$. In all the examples, N_i has been set equal to $n_{\rm atoms}$, the total number of atoms. The ninth and tenth columns show $\langle \Delta r\rangle$ values derived from Luzzati (1952) and Read (1986) plots described later in Section 18.5.8.

The first entry is for crambin at 0.83 Å resolution and 130 K (Stec *et al.*, 1995). Their results were obtained from an unrestrained full-matrix anisotropic refinement. Inversion of the full matrix gave s.u.'s $\sigma_{\rm diff}(x) = 0.0096$ Å for backbone atoms, 0.0168 Å for side-chain atoms and 0.0409 Å for solvent atoms, with an average for all atoms of 0.022 Å. The DPI $\sigma(r, B_{\rm avg}) = 0.021$ Å corresponds to $\sigma(x) = 0.012$ Å, which is satisfactorily intermediate between the full-matrix values for the backbone and side-chain atoms.

Sevcik *et al.* (1996) carried out restrained anisotropic full-matrix refinements on data from two slightly different crystals of ribonuclease Sa, with $d_{\min}$ of 1.15 and 1.20 Å. They inverted full-matrix blocks containing parameters of 20 residues to estimate coordinate errors. The overall r.m.s. coordinate error for protein atoms is given as 0.03 Å, and for all atoms (including waters and ligands) as 0.07 Å for MGMP and 0.05 Å for MSA. The DPI gives $\sigma(r, B_{\rm avg}) = 0.05$ Å for both structures.

The next entries concern the two lower-resolution (1.8 and 1.95 Å) studies of TGF-β2 (Daopin *et al.*, 1994). The DPI gives $\sigma(r) = 0.16$ Å for 1TGI and 0.24 Å for 1TGF. This indicates an

r.m.s. position difference between the structures for atoms with $B_i = B_{\rm avg}$ of $(0.16^2 + 0.24^2)^{1/2} = 0.29$ Å. Daopin *et al.* reported the differences between the two determinations, omitting poor parts, as $\langle\Delta r\rangle_{\rm rms} = 0.15$ Å (main chain) and 0.29 Å (all atoms).

Human diferric lactoferrin (Haridas *et al.*, 1995) is an example of a large protein at the lower resolution of 2.2 Å, with a high value of $(N_i/p)^{1/2}$, leading to $\sigma(r, B_{\rm avg}) = 0.43$ Å.

Three crystal forms of thaumatin were studied by Ko *et al.* (1994). The orthorhombic and tetragonal forms diffracted to 1.75 Å, but the monoclinic $C2$ form diffracted only to 2.6 Å. The structures with 1552 protein atoms were successfully refined with restraints by *XPLOR* and *TNT*. For the monoclinic form, the number of parameters exceeds the number of diffraction observations, so (N_i/p) is negative and no estimate by (18.5.6.9) of the diffraction-data-only error is possible. The DPI (18.5.6.9) gives 0.17 and 0.16 Å for the orthorhombic and tetragonal forms, respectively.

18.5.7.3. Examples of the DPI using R_{free}

As in the case of monoclinic thaumatin, for low-resolution structures the number of parameters may exceed the number of diffraction data. To circumvent this difficulty, it was proposed in Section 18.5.6.3 to replace $p = n_{\rm obs} - n_{\rm params}$ by $n_{\rm obs}$ and R by $R_{\rm free}$ in a revised formula (18.5.6.10) for the DPI. Table 18.5.7.3 shows examples for some structures for which both R and $R_{\rm free}$ were available. The second row for each protein shows the alternative values for $(N_i/n_{\rm obs})^{1/2}$, $R_{\rm free}$ and the DPI $\sigma(r, B_{\rm avg})$ from (18.5.6.10).

For the structures with $d_{\min} \leq 2.0$ Å, the DPI is much the same whether it is based on R or $R_{\rm free}$.

Tickle *et al.* (1998*a*) have made full-matrix error estimates for isotropic restrained refinements of γB-crystallin with $d_{\min} = 1.49$ Å and of βB2-crystallin with $d_{\min} = 2.10$ Å. The DPI $\sigma(r, B_{\rm avg})$ calculated for the two structures is 0.14 and 0.25 Å with R in (18.5.6.9), and 0.14 and 0.22 Å with $R_{\rm free}$ in (18.5.6.10). The full-matrix weighted averages of $\sigma_{\rm res}(r)$ for all protein atoms were 0.10 and 0.15 Å, for only main-chain atoms 0.05 and 0.08 Å, for side-chain atoms 0.14 and 0.20 Å, and for water oxygens 0.27 and 0.35 Å. Again, the DPI gives reasonable overall indices for the quality of the structures.

For the complex of bovine ribonuclease A and porcine ribonuclease inhibitor (Kobe & Deisenhofer, 1995) with $d_{\min} =$ 2.50 Å, the number of reflections is only just larger than the number of parameters, so that $(N_i/p)^{1/2} = 1.922$ is very large, and the DPI with R gives an unrealistic 1.85 Å. With $R_{\rm free}$, $\sigma(r, B_{\rm avg}) = 0.69$ Å.

The HyHEL-5–lysozyme complex (Cohen *et al.*, 1996) had $d_{\min} = 2.65$ Å. Here the number of reflections is less than the number of parameters, but the $R_{\rm free}$ formula gives $\sigma(r, B_{\rm avg}) =$ 0.69 Å.

18.5.7.4. Comments on the diffraction-component precision index

The DPI (18.5.6.9) or (18.5.6.10) provides a very simple formula for $\sigma(r, B_{\rm avg})$. It is based on a very rough approximation to a diagonal element of the diffraction-data-only matrix. Using a diagonal element is a reasonable approximation for atomic resolution structures, but for low-resolution structures there will be significant off-diagonal terms between overlapping atoms. The effect can be simulated in the two-atom protein model of Section 18.5.3.2 by introducing positive off-diagonal elements into the diffraction-data matrix (18.5.3.3). As expected, $\sigma^2_{\rm diff}(x_i)$ is increased. So the DPI will be an underestimate of the diffraction component in low-resolution structures.

However, the true restrained variance $\sigma^2_{\rm res}(x_i)$ in the new counterpart of (18.5.3.12) remains less than the diagonal diffraction result (18.5.3.11) $\sigma^2_{\rm diff}(x_i) = 1/a$. Thus for low-resolution structures, the DPI should be an overestimate of the true precision given by a restrained full-matrix calculation (where the restraints act to hold the overlapping atoms apart). This is confirmed by the results for the 2.1 Å study of βB2-crystallin (Tickle *et al.*, 1998*a*) discussed in Section 18.5.7.3 and Table 18.5.7.3. The restrained full-matrix average for all protein atoms was $\sigma_{\rm res}(r) = 0.15$ Å, compared with the DPI 0.25 Å (on R) or 0.22 Å (on $R_{\rm free}$). The ratio between the unrestrained DPI and the restrained full-matrix average is consistent with a view of a low-resolution protein as a chain of effectively rigid peptide groups. The ratio no doubt gets much worse for resolutions of 3 Å and above.

The DPI estimate of $\sigma(r, B_{\rm avg})$ is given by a formula of 'back-of-an-envelope' simplicity. $B_{\rm avg}$ is taken to be the average B for fully occupied sites, but the weights implicit in the averaging are not well defined in the derivation of the DPI. Thus the DPI should perhaps be regarded as simply offering an estimate of a typical $\sigma_{\rm diff}(r)$ for a carbon or nitrogen atom with a mid-range B.

Table 18.5.8.1
$R = \langle|\Delta F|\rangle/\langle|F|\rangle$ as a function of $s\langle\Delta r\rangle$ in the Luzzati model for three-dimensional noncentrosymmetric structures ($s = 2\sin\theta/\lambda$)

$s\langle\Delta r\rangle$	R	$s\langle\Delta r\rangle$	R
0.00	0.000	0.10	0.237
0.01	0.025	0.12	0.281
0.02	0.050	0.14	0.319
0.03	0.074	0.16	0.353
0.04	0.098	0.18	0.385
0.05	0.122	0.20	0.414
0.06	0.145	0.25	0.474
0.07	0.168	0.30	0.518
0.08	0.191	0.35	0.548
0.09	0.214	∞	0.586

From the evidence of the tables in this section, except at low resolution, it seems to give a useful overall indication of protein precision, even in restrained refinements.

The DPI evidently provides a method for the comparative ranking of different structure determinations. In this regard it is a complement to the general use of $d_{\rm min}$ as a quick indicator of possible structural quality.

Note that (18.5.6.3) and (18.5.6.4) offer scope for making individual error estimates for atoms of different B and Z.

18.5.8. Luzzati plots

18.5.8.1. *Luzzati's theory*

Luzzati (1952) provided a theory for estimating, at any stage of a refinement, the average positional shifts which would be needed in an idealized refinement to reach $R = 0$. He did not provide a theory for estimating positional errors at the end of a normal refinement.

(1) His theory assumed that the $F_{\rm obs}$ had no errors, and that the $F_{\rm calc}$ model (scattering factors, thermal parameters *etc.*) was perfect, apart from coordinate errors.
(2) The Gaussian probability distribution for these coordinate errors was assumed to be the *same for all atoms*, independent of Z or B.
(3) The atoms were not required to be identical, and the position errors were not required to be small.

Luzzati gave families of curves for R *versus* $2\sin\theta/\lambda$ for varying average positional errors $\langle\Delta r\rangle$ for both centrosymmetric and noncentrosymmetric structures. The curves do not depend on the number N of atoms in the cell. They all rise from $R = 0$ at $2\sin\theta/\lambda = 0$ to the Wilson (1950) values 0.828 and 0.586 for random structures at high $2\sin\theta/\lambda$. Table 18.5.8.1 gives $R = \langle|\Delta F|\rangle/\langle|F|\rangle$ as a function of $s\langle\Delta r\rangle$ for three-dimensional noncentrosymmetric structures.

In a footnote (p. 807), Luzzati suggested that at the end of a normal refinement (with R nonzero due to experimental and model errors, *etc.*), the curves would indicate an upper limit for $\langle\Delta r\rangle$. He noted that typical small-molecule $\sigma(r)$'s of 0.01–0.02 Å, if used as $\langle\Delta r\rangle$ in the plots, would give much smaller R's than are found at the end of a refinement.

As examples, the Luzzati plots for the two structures of TGF-β2 are shown in Fig. 18.5.8.1. Daopin *et al.* (1994) inferred average $\langle\Delta r\rangle$'s around 0.21 Å for 1TGI and 0.23 Å for 1TGF.

Of the three Luzzati assumptions summarized above, the most attractive is the third, which does not require the atoms to be identical nor the position errors to be small. For proteins, there are very obvious difficulties with assumption (2). Errors do depend very strongly on Z and B. In the high-angle data shells, atoms with large B's contribute neither to ΔF nor to $|F|$, and so have no effect on R in these shells. In their important paper on protein accuracy, Chambers & Stroud (1979) said 'the [Luzzati] estimate derived from reflections in this range applies mainly to [the] best determined atoms.'

Thus a Luzzati plot seems to allow a cautious upper-limit statement about the precision of the best parts of a structure, but it gives little indication for the poor parts.

One reason for the past popularity of Luzzati plots has been that the R values for the middle and outer shells of a structure often roughly follow a Luzzati curve. Evidently, the effective average $\langle\Delta r\rangle$ for the structure must be decreasing as $2\sin\theta/\lambda$ increases, since atoms of high B are ceasing to contribute, whereas the proportionate experimental errors must be increasing. This also suggests that the upper limit for $\langle\Delta r\rangle$ for the low-B atoms could be estimated from the lowest Luzzati theoretical curve touched by the experimental R plot. Thus in Fig. 18.5.8.1 the upper limits for the low-B atoms could be taken as 0.18 and 0.21 Å, rather than the 0.21 and 0.23 Å chosen by Daopin *et al.*

From the introduction of $R_{\rm free}$ by Brünger (1992) and the discussion of $R_{\rm free}$ by Tickle *et al.* (1998*b*), it can be seen that Luzzati plots should be based on a residual more akin to $R_{\rm free}$ than R in order to avoid bias from the fitting of data.

The mean positional error $\langle\Delta r\rangle$ of atoms can also be estimated from the σ_A plots of Read (1986, 1990). This method arose from Read's analysis of improved Fourier coefficients for maps using phases from partial structures with errors. It is preferable in several respects to the Luzzati method, but like the Luzzati method it assumes that the coordinate distribution is the same for all atoms. Luzzati and/or Read estimates of $\langle\Delta r\rangle$ are available for some of the structures in Tables 18.5.7.2 and 18.5.7.3. Often, the two estimates are not greatly different.

18.5.8.2. *Statistical reinterpretation of Luzzati plots*

Luzzati plots are fundamentally different from other statistical estimates of error. The Luzzati theory applies to an idealized incomplete refinement and estimates the average shifts needed to reach $R = 0$. In the least-squares method, the equations for shifts are quite different from the equations for estimating variances in a converged refinement. However, Luzzati-style plots of R *versus* $2\sin\theta/\lambda$ can be reinterpreted to give statistically based estimates of $\sigma(x)$.

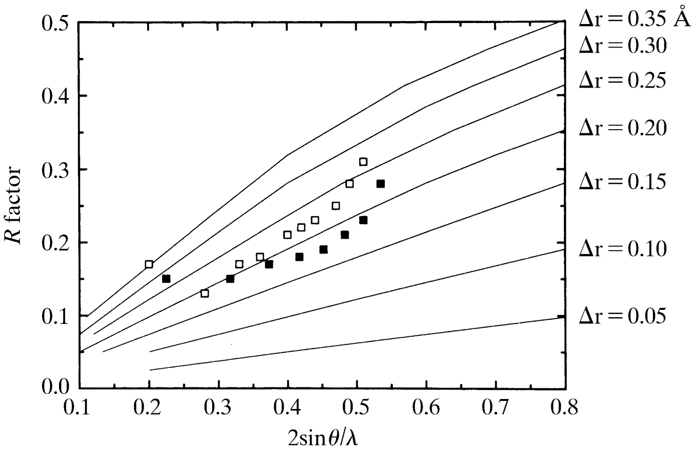

Figure 18.5.8.1
Luzzati plots showing the refined R factor as a function of resolution for 1TGI (solid squares) and 1TGF (open squares) (Daopin *et al.*, 1994).

During Cruickshank's (1960) derivation of the approximate equation (18.5.6.2) for $\sigma(x)$ in diagonal least squares, he reached an intermediate equation

$$\sigma^2(x) = N_i \bigg/ \left[4 \sum_{\rm obs} (s^2/R^2)\right]. \qquad (18.5.8.1)$$

He then assumed R to be independent of s $(= 2\sin\theta/\lambda)$ and took R outside the summation to reach (18.5.6.2) above.

Luzzati (1952) calculated the acentric residual R as a function of $\langle\Delta r\rangle$, the average radial error of the atomic positions. His analysis shows that R is a linear function of s and $\langle\Delta r\rangle$ for a substantial range of $s\langle\Delta r\rangle$, with

$$R(s,\ \langle\Delta r\rangle) = (2\pi)^{1/2} s\langle\Delta r\rangle. \qquad (18.5.8.2)$$

The theoretical Luzzati plots of R are nearly linear for small-to-medium $s = 2\sin\theta/\lambda$ (see Fig. 18.5.8.1). If we substitute this R in the least-squares estimate (18.5.8.1) and use the three-dimensional-Gaussian relation $\sigma(r) = 1.085\langle\Delta r\rangle$, some manipulation (Cruickshank, 1999) along the lines of Section 18.5.6 eventually yields a statistically based formula,

$$\sigma_{\rm LS,Luzz}(r) = 1.33(N_i/p)^{1/2}[R(s_m)/s_m], \qquad (18.5.8.3)$$

where $R(s_m)$ is the value of R at some value of $s = s_m$ on the selected Luzzati curve. Equation (18.5.8.3) provides a means of making a very rough statistical estimate of error for an atom with $B = B_{\rm avg}$ (the average B for fully occupied sites) from a plot of R *versus* $2\sin\theta/\lambda$.

The corresponding equation involving $R_{\rm free}$ is

$$\sigma_{\rm LS,Luzz}(r) = 1.33(N_i/n_{\rm obs})^{1/2}[R_{\rm free}(s_m)/s_m]. \qquad (18.5.8.4)$$

18.5.8.3. Comments on Luzzati plots

Protein structures always show a great range of B values. The Luzzati theory effectively assumes that all atoms have the same B. Nonetheless, the Luzzati method applied to high-angle data shells does provide an upper limit for $\langle\Delta r\rangle$ for the atoms with low B. It is an upper limit since experimental errors and model imperfections are not allowed for in the theory.

Low-resolution structures can be determined validly by using restraints, even though the number of diffraction observations is less than the number of atomic coordinates. The Luzzati method, based preferably on $R_{\rm free}$, can be applied to the atoms of low B in such structures. As the number of observations increases, and the resolution improves, the Luzzati $\langle\Delta r\rangle$ increasingly overestimates the true $\sigma(r)$ of the low-B atoms.

In the use of Luzzati plots, the method of refinement, and its degree of convergence, is irrelevant. A Luzzati plot is a statement for the low-B atoms about the maximum errors associated with a given structure, whether converged or not.

Chapter 18.6. *CNS*, a program system for structure-determination and refinement

A. T. Brunger, P. D. Adams, W. L. DeLano, P. Gros, R. W. Grosse-Kunstleve, J.-S. Jiang, N. S. Pannu, R. J. Read, L. M. Rice and T. Simonson

18.6.1. Introduction

We have developed a new and advanced software system, the *Crystallography & NMR System* (CNS), for crystallographic and NMR structure determination (Brünger *et al.*, 1998). The goals of CNS are: (1) to create a flexible computational framework for exploration of new approaches to structure determination; (2) to provide tools for structure solution of difficult or large structures; (3) to develop models for analysing structural and dynamical properties of macromolecules; and (4) to integrate all sources of information into all stages of the structure-determination process.

To meet these goals, algorithms were moved from the source code into a symbolic structure-determination language which represents a new concept in computational crystallography. The high-level CNS computing language allows definition of symbolic target functions, data structures, procedures and modules. The CNS program acts as an interpreter for the high-level CNS language and includes hard-wired functions for efficient processing of computing-intensive tasks. Methods and algorithms are therefore more clearly defined and easier to adapt to new and challenging problems. The result is a multi-level system which provides maximum flexibility to the user (Fig. 18.6.1.1). The CNS language provides a common framework for nearly all computational procedures of structure determination. A comprehensive set of crystallographic procedures for phasing, density modification and refinement has been implemented in this language. Task-oriented input files written in the CNS language, which can also be accessed through an HTML graphical interface (Graham, 1995), are available to carry out these procedures.

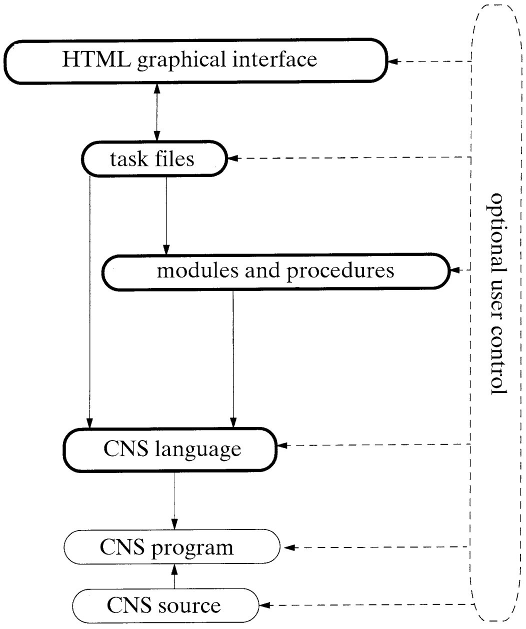

Figure 18.6.1.1
CNS consists of five layers which are under user control. The high-level HTML graphical interface interacts with the task-oriented input files. The task files use the CNS language and the modules. The modules contain CNS language statements. The CNS language is interpreted by the CNS Fortran77 program. The program performs the data manipulations, data operations and 'hard-wired' algorithms.

18.6.2. The CNS language

One of the key features of the CNS language is symbolic data structure manipulation, for example,

```
xray
  do (pa = −2 * (amplitude(fp)^2 + amplitude(fh)^2
           − amplitude(fph) ^2) * amplitude(fp)
           * real(fh)/(3 * v^2 + 4 * (amplitude(fph)^2
           + sph^2) * v)) (acentric)
end
```

(18.6.2.1)

which is equivalent to the following mathematical expression for all acentric indices **h**,

$$p_a(\mathbf{h}) = 2\frac{-[|\mathbf{f}_p(\mathbf{h})|^2 + |\mathbf{f}_h(\mathbf{h})|^2 - |\mathbf{f}_{ph}(\mathbf{h})|^2]|\mathbf{f}_p(\mathbf{h})|\{[\mathbf{f}_h(\mathbf{h}) + \mathbf{f}_h(\mathbf{h})^*]/2\}}{3v(\mathbf{h})^2 + 4[|\mathbf{f}_{ph}(\mathbf{h})|^2 + s_{ph}(\mathbf{h})^2]v(\mathbf{h})}, \tag{18.6.2.2}$$

where $\mathbf{f}_p$ ['fp' in equation (18.6.2.1)] is the 'native' structure-factor array, $\mathbf{f}_{ph}$ ['fph' in equation (18.6.2.1)] is the derivative structure-factor array, s_{ph} ['sph' in equation (18.6.2.1)] is the corresponding experimental σ, v is the expectation value for the lack of closure (including lack of isomorphism and errors in the heavy-atom model), and $\mathbf{f}_h$ ['fh' in equation (18.6.2.1)] is the calculated heavy-atom structure-factor array. This expression computes the $A_{\rm iso}$ coefficient of the phase probability distribution for single isomorphous replacement described by Hendrickson & Lattman (1970) and Blundell & Johnson (1976).

The expression in equation (18.6.2.1) is computed for the specified subset of reflections '(acentric)'. This expression means that only the selected (in this case all acentric) reflections are used. More sophisticated selections are possible, *e.g.*

```
(amplitude(fp)>2 * sh and amplitude(fph)>2 * sph
  and d> = 3)
```

(18.6.2.3)

selects all reflections with Bragg spacing, d, greater than 3 Å for which both native (fp) and derivative (fph) amplitudes are greater than two times their corresponding σ values ('sh' and 'sph', respectively). Extensive use of this structure-factor selection facility is made for cross-validating statistical properties, such as R values (Brünger, 1992), σ_A values (Kleywegt & Brünger, 1996; Read, 1997) and maximum-likelihood functions (Pannu & Read, 1996; Adams *et al.*, 1997).

Similar operations exist for electron-density maps, *e.g.*

```
xray
  do (map = 0) (map < 0.1)
end
```

(18.6.2.4)

is an example of a truncation operation: all map values less than

```
evaluate ( $crystal_lattice.space_group     = "P2(1)2(1)2(1)" )
evaluate ( $crystal_lattice.unit_cell.a     = 61.76           )
evaluate ( $crystal_lattice.unit_cell.b     = 40.73           )
evaluate ( $crystal_lattice.unit_cell.c     = 26.74           )
evaluate ( $crystal_lattice.unit_cell.alpha = 90              )
evaluate ( $crystal_lattice.unit_cell.beta  = 90              )
evaluate ( $crystal_lattice.unit_cell.gamma = 90              )
```

(*a*)

```
define (
   &crystal_lattice.space_group     = P2(1)2(1)2(1) ;
   &crystal_lattice.unit_cell.a     = 61.76 ;
   &crystal_lattice.unit_cell.b     = 40.73 ;
   &crystal_lattice.unit_cell.c     = 26.74 ;
   &crystal_lattice.unit_cell.alpha = 90 ;
   &crystal_lattice.unit_cell.beta  = 90 ;
   &crystal_lattice.unit_cell.gamma = 90 ;
)
```

(*b*)

Figure 18.6.3.1
Examples of compound symbols and compound parameters. (*a*) The ‘evaluate’ statement is used to define typed symbols (strings, numbers and logicals). Symbol names are in bold. (*b*) The ‘define’ statement is used to define untyped parameters. Each parameter entry is terminated by a semicolon. The compound base name ‘crystal_lattice’ has a number of sub-levels, such as ‘space_group’ and the ‘unit_cell’ parameters. ‘unit_cell’ is itself base to a number of sub-levels, such as ‘a’ and ‘alpha’. Parameter names are in bold.

```
do (eobs=norm(amplitude(fobs)))                              ( test_set )
do (ecalc=norm(amplitude(fcalc)))                            ( test_set )
do (sigmaA=sigacv(eobs,ecalc))                               ( test_set )
do (sigmaD=sqrt(save(amplitude(fobs))^2 (1-sigmaA^2)))       ( test_set )
do (D= sigmaA * sqrt(save(amplitude(fobs))^2  /
            save(amplitude(fcalc)^2)))                       ( test_set )

do (sigmaA=sum(sigmaA*test)/ max(1,sum(test)))               ( all )
do (sigmaD=sum(sigmaD*test)/ max(1,sum(test)))               ( all )
do (D=sum(D*test)/ max(1,sum(test)))                         ( all )
```

Figure 18.6.4.1
Example for statistical operations provided by the CNS language. ‘norm’, ‘sigacv’, ‘save’ and ‘sum’ are functions that are computed internally by the CNS program. Binwise operations are in italics (‘sigacv’, ‘save’ and ‘sum’). The result for a particular bin is stored in all elements belonging to the bin. The σ_A (‘sigmaA’) parameters are computed in binwise resolution shells. The σ_Δ (‘sigmaD’) and D parameters are then computed from σ_A and binwise averages involving $|\mathbf{F}_o|^2$ and $|\mathbf{F}_c|^2$. The binwise results are expanded to all reflections by the last three statements. ‘test’ is an array that is 1 for all reflections in the test set and 0 otherwise. ‘sum’ is a binwise operation on all reflections with the same partitioning used for the test set.

0.1 are set to 0. Atoms can be selected based on a number of atomic properties and descriptors, *e.g.*

```
do (b = 10)(residue 1:40 and
            (name ca or name n or name c or name o))
```
(18.6.2.5)

sets the B factors of all polypeptide backbone atoms of residues 1 through 40 to 10 Å^2.

Operations exist between data structures, *e.g.* real- and reciprocal-space arrays, and atom properties. For example, Fourier transformations between real and reciprocal space can be accomplished by the following CNS commands:

```
xray
  mapresolution infinity 3.
  fft grid 0.3333 end
  do (map = ft(f_cal)) (acentric)
end
```
(18.6.2.6)

which computes a map on a 1 Å grid by Fourier transformation of the ‘f_cal’ array for all acentric reflections.

Atoms can be associated with calculated structure factors, *e.g.*

```
associate f_cal (residue 1:50)
```
(18.6.2.7)

This statement will associate the reciprocal-space array ‘f_cal’ with the atoms belonging to residues 1 through 50. These structure-factor associations are used in the symbolic target functions described below.

There are no predefined reciprocal- or real-space arrays in CNS. Dynamic memory allocation allows one to carry out operations on arbitrarily large data sets with many individual entries (*e.g.* derivative diffraction data) without the need to recompile the source code. The various reciprocal-space structure-factor arrays must therefore be declared and their type specified prior to invoking them. For example, a reciprocal-space array with real values, such as observed amplitudes, is declared by

```
declare name = fobs type = real domain = reciprocal end
```
(18.6.2.8)

Reciprocal-space arrays can be grouped. For example, Hendrickson & Lattman (1970) coefficients are represented as a group of four reciprocal-space structure-factor arrays,

```
group type = hl object = pa object = pb
  object = pc object = pd end
```
(18.6.2.9)

where ‘pa’, ‘pb’, ‘pc’ and ‘pd’ refer to the individual arrays. This group statement indicates to CNS that the specified arrays need to be transformed together when reflection indices are changed, *e.g.* during expansion of the diffraction data to space group *P*1.

18.6.3. Symbols and parameters

The CNS language supports two types of data elements which may be used to store and retrieve information. *Symbols* are typed variables, such as numbers, character strings of restricted length and logicals. *Parameters* are untyped data elements of arbitrary length that may contain collections of CNS commands, numbers, strings or symbols.

Symbols are denoted by a dollar sign ($), and parameters by an ampersand (&). Symbols and parameters may contain a single data element, or they may be a *compound* data structure of arbitrary complexity. The hierarchy of these data structures is denoted using a period (.). Figs. 18.6.3.1(*a*) and (*b*) demonstrate how crystal-lattice information can be stored in compound symbols and parameters, respectively. The information stored in symbols or parameters can be retrieved by simply referring to them within a CNS command: the symbol or parameter name is substituted by its content. Symbol substitution of portions of the compound names (*e.g.* ‘&crystal_lattice.unit_cell.$para’) allows one to carry out conditional and iterative operations on data structures, such as matrix multiplication.

18.6.4. Statistical functions

The CNS language contains a number of statistical operations, such as binwise averages and summations. The resolution bins are defined by a central facility in CNS.

Fig. 18.6.4.1 shows how σ_A, σ_Δ and D (Read, 1986, 1990) are computed from the observed structure factors (‘fobs’) and the calculated model structure factors (‘fcalc’) using the CNS statistical operations. The first five operations are performed for the reflections in the test set, while the last three operations expand the results to all reflections. The ‘norm’ function computes normalized structure-factor amplitudes for the specified argu-

```
associate f_h_1 <atom-selection-1>
associate f_h_2 <atom-selection-2>
associate f_h_3 <atom-selection-3>

target=(
         (abs(f_h_1+f_p)-f_ph_1)^2 / (2*v_1) +
         (abs(f_h_2+f_p)-f_ph_2)^2 / (2*v_2) +
         (abs(f_h_3+f_p)-f_ph_3)^2 / (2*v_3)
       )

dtarget(f_h_1)=
        (
         2*(abs(f_h_1+f_p)-f_ph_1)
           *(f_h_1+f_p)/abs(f_h_1+f_p) / (2*v_1)
         )

dtarget(f_h_2)=
        (
         2*(abs(f_h_2+f_p)-f_ph_2)
           *(f_h_2+f_p)/abs(f_h_2+f_p) / (2*v_2)
         )

dtarget(f_h_3)=
        (
         2*(abs(f_h_3+f_p)-f_ph_3)
           *(f_h_3+f_p)/abs(f_h_3+f_p) / (2*v_3)

tselection=<selection>
cvselection=<selection>
```

(*a*)

```
associate fcalc1 <atom-selection1>
associate fcalc2 <atom-selection2>

target=( abs(fobs) - sqrt(abs(fcalc1)^2+abs(fcalc2)^2))^2 )

dtarget(fcalc1)=( -2 *
            (abs(fobs)-sqrt(abs(fcalc1)^2+abs(fcalc2)^2)) *
              (fcalc1/(sqrt(abs(fcalc1)^2+abs(fcalc2)^2))))

dtarget(fcalc2)=( -2 *
            (abs(fobs)-sqrt(abs(fcalc1)^2+abs(fcalc2)^2)) *
              (fcalc2/(sqrt(abs(fcalc1)^2+abs(fcalc2)^2))))

tselection=<selection>
cvselection=<selection>
```

(*b*)

Figure 18.6.5.1
Examples of symbolic definition of a refinement target function and its derivatives with respect to the calculated structure-factor arrays. (*a*) Simultaneous refinement of heavy-atom sites of three derivatives. The target function is defined by the 'target' expression. 'f_h_1', 'f_h_2' and 'f_h_3' (in bold) are complex structure factors corresponding to three sets of heavy atoms that are specified using atom selections [equation (18.6.2.7)]. The target function and its derivatives with respect to the three structure-factor arrays are defined symbolically using the structure-factor amplitudes of the native crystal, 'f_p', those of the derivatives, 'f_ph_1', 'f_ph_2', 'f_ph_3', the complex structure factors of the heavy-atom models, 'f_h_1', 'f_h_2', 'f_h_3', and the corresponding lack-of-closure variances, 'v_1', 'v_2' and 'v_3'. The summation over the selected stucture factors ('tselection') is performed implicitly. (*b*) Refinement of two independent models against perfectly twinned data. 'fcalc1' and 'fcalc2' are complex structure factors for the models that are related by a twinning operation (in bold). The target function and its derivatives with respect to the two structure-factor arrays are explicitly defined.

ments. The 'sigacv' function evaluates σ_A from the normalized structure factors. The 'save' function computes the statistical average

$$\text{save}(f) = \frac{\sum_{hkl} f_{hkl}(w/\varepsilon)}{\sum_{hkl} w}, \qquad (18.6.4.1)$$

where w is 1 and 2 for centric and acentric reflections, respectively, and ε is the statistical weight. The averages are computed binwise, and the result for a particular bin is stored in all selected reflections belonging to the bin.

18.6.5. Symbolic target function

One of the key innovative features of CNS is the ability to symbolically define target functions and their first derivatives for crystallographic searches and refinement. This allows one conveniently to implement new crystallographic methodologies as they are being developed.

The power of symbolic target functions is illustrated by two examples. In the first example, a target function is defined for simultaneous heavy-atom parameter refinement of three derivatives. The sites for each of the three derivatives can be disjoint or identical, depending on the particular situation. For simplicity, the Blow & Crick (1959) approach is used, although maximum-likelihood targets are also possible (see below). The heavy-atom sites are refined against the target

$$\sum_{hkl} \frac{(|\mathbf{F}_{h_1} + \mathbf{F}_p| - |\mathbf{F}_{ph_1}|)^2}{2v_1} + \frac{(|\mathbf{F}_{h_2} + \mathbf{F}_p| - |\mathbf{F}_{ph_2}|)^2}{2v_2} + \frac{(|\mathbf{F}_{h_3} + \mathbf{F}_p| - |\mathbf{F}_{ph_3}|)^2}{2v_3}. \qquad (18.6.5.1)$$

$\mathbf{F}_{h_1}$, $\mathbf{F}_{h_2}$ and $\mathbf{F}_{h_3}$ are complex structure factors corresponding to the three sets of heavy-atom sites, $\mathbf{F}_p$ represents the structure factors of the native crystal, $|\mathbf{F}_{ph_1}|$, $|\mathbf{F}_{ph_2}|$ and $|\mathbf{F}_{ph_3}|$ are the structure-factor amplitudes of the derivatives, and v_1, v_2 and v_3 are the variances of the three lack-of-closure expressions. The corresponding target expression and its first derivatives with respect to the calculated structure factors are shown in Fig. 18.6.5.1(*a*). The derivatives of the target function with respect to each of the three associated structure-factor arrays are specified with the 'dtarget' expressions. The 'tselection' statement specifies the selected subset of reflections to be used in the target function (*e.g.* excluding outliers), and the 'cvselection' statement specifies a subset of reflections to be used for cross-validation (Brünger, 1992) (*i.e.* the subset is not used during refinement but only as a monitor for the progress of refinement).

The second example is the refinement of a perfectly twinned crystal with overlapping reflections from two independent crystal lattices. Refinement of the model is carried out against the residual

$$\sum_{hkl} |\mathbf{F}_{\text{obs}}| - (|\mathbf{F}_{\text{calc1}}|^2 + |\mathbf{F}_{\text{calc2}}|^2)^{1/2}. \qquad (18.6.5.2)$$

The symbolic definition of this target is shown in Fig. 18.6.5.1(*b*). The twinning operation itself is imposed as a relationship between the two sets of selected atoms (not shown). This example assumes that the two calculated structure-factor arrays ('fcalc1' and 'fcalc2') that correspond to the two lattices have been appropriately scaled with respect to the observed structure factors, and the twinning fractions have been incorporated into the scale factors. However, a more sophisticated target function could be defined which incorporates scaling.

A major advantage of the symbolic definition of the target function and its derivatives is that any arbitrary function of structure-factor arrays can be used. This means that the scope of possible targets is not limited to least-squares targets. Symbolic definition of numerical integration over unknown variables (such as phase angles) is also possible. Thus, even complicated maximum-likelihood target functions (Bricogne, 1984; Otwinowski, 1991; Pannu & Read, 1996; Pannu *et al.*, 1998) can be defined using the CNS language. This is particularly valuable at the prototype stage. For greater efficiency, the standard maximum-likelihood targets are provided through CNS source code which can be accessed as functions in the CNS language. For example, the maximum-likelihood target function MLF (Pannu & Read, 1996) and its derivative with respect to the calculated structure factors are defined as

```
module { compute_unit_cell_volume }
(
   &cell;
   &volume;
)

evaluate ( $cabg.1=cos(&cell.alpha) )
evaluate ( $sabg.1=sin(&cell.alpha) )

evaluate ( $cabg.2=cos(&cell.beta) )
evaluate ( $sabg.2=sin(&cell.beta) )

evaluate ( $cabg.3=cos(&cell.gamma) )
evaluate ( $sabg.3=sin(&cell.gamma) )

evaluate ( &volume=&cell.a * &cell.b * &cell.c *
                   sqrt(1+2*$cabg.1*$cabg.2*$cabg.3
                        -$cabg.1^2-$cabg.2^2-$cabg.3^2) )
```

Figure 18.6.6.1
Use of compound parameters within a module. This module computes the unit-cell volume (Stout & Jensen, 1989) from the unit-cell geometry. Input and output parameter base names are in bold. Local symbols, such as cabg.1, are defined through 'evaluate' statements. The result is stored in the parameter '&volume' which is passed to the invoking task file or module.

$$\begin{aligned}\texttt{target} &= \texttt{(mlf (fobs,sigma,(fcalc + fbulk),}\\ &\qquad \texttt{d,sigma\_delta))}\\ \texttt{dtarget} &= \texttt{(dmlf (fobs,sigma,(fcalc + fbulk),}\\ &\qquad \texttt{d,sigma\_delta))}\end{aligned}\tag{18.6.5.3}$$

where 'mlf( )' and 'dmlf( )' refer to internal maximum-likelihood functions, 'fobs' and 'sigma' are the observed structure-factor amplitudes and corresponding σ values, 'fcalc' is the (complex) calculated structure-factor array, 'fbulk' is the structure-factor array for a bulk solvent model, and 'd' and 'sigma_delta' are the cross-validated D and σ_Δ functions (Read, 1990; Kleywegt & Brünger, 1996; Read, 1997) which are precomputed prior to invoking the MLF target function using the test set of reflections. The availability of internal Fortran subroutines for the most computing-intensive target functions and the symbolic definitions involving structure-factor arrays allow for maximal flexibility and efficiency. Other examples of available maximum-likelihood target functions include MLI (intensity-based maximum-likelihood refinement), MLHL [crystallographic model refinement with prior phase information (Pannu *et al.*, 1998)], and maximum-likelihood heavy-atom parameter refinement for multiple isomorphous replacement (Otwinowski, 1991) and MAD phasing (Hendrickson, 1991; Burling *et al.*, 1996). Work is in progress to define target functions that include correlations between different heavy-atom derivatives (Read, 1994).

18.6.6. Modules and procedures

Modules exist as separate files and contain collections of CNS commands related to a particular task. In contrast, *procedures* can be defined and invoked from within any file. Modules and procedures share a similar parameter-passing mechanism for both input and output. Modules and procedures make it possible to write programs in the CNS language in a manner similar to that of a computing language, such as Fortran or C. CNS modules and procedures have defined sets of input (and output) parameters that are passed into them (or returned) when they are invoked. This enables long collections of CNS language statements to be broken down into modules for greater clarity of the underlying algorithm.

Parameters passed into a module or procedure inherit the scope of the calling task file or module, and thus they exhibit a behaviour analogous to most computing languages. Symbols defined within a module or procedure are purely local variables.

```
module { phase_distribution }
     (
   &fp;  {input: native data}
   &sp;  {input: native sigma}
   &sel; {input: selection of structure factors}
   &fh;  {input: name of heavy atom structure factors}
   &fph; {input: name of derivative data array}
   &sph; {input: name of derivative's sigma array}
   &var; {input: lack-of-isomorphism plus measurement errors}
   &pa;  {output: Hendrickson and Lattman A array}
   &pb;  {output: Hendrickson and Lattman B array}
   &pc;  {output: Hendrickson and Lattman C array}
   &pd;  {output: Hendrickson and Lattman D array}
     )

do (&pa= (cos(centric_phase)*(
        -(abs(&fh+combine(abs(&fp),centric_phase))-abs(&fph))^2/(2*&var)
        +(abs(&fh-combine(abs(&fp),centric_phase))-abs(&fph))^2/(2*&var)))
  ( centric and &sel )

do (&pb=(sin(centric_phase)*(
        -(abs(&fh+combine(abs(&fp),centric_phase))-abs(&fph))^2/(2*&var)
        +(abs(&fh-combine(abs(&fp),centric_phase))-abs(&fph))^2/(2*&var)))
  ( centric and &sel )

do (&pc=0) (centric and &sel)

do (&pd=0) (centric and &sel)

do (&pa=-2 * (amplitude(&fp)^2 + amplitude(&fh)^2 - amplitude(&fph)^2 )
          * amplitude(&fp) * real(&fh)/
          (3 * &var^2 + 4 * (amplitude(&fph)^2+&sph^2) * &var))
  ( acentric and &sel )

do (&pb=-2 * (amplitude(&fp)^2 + amplitude(&fh)^2 - amplitude(&fph)^2 )
          * amplitude(&fp) * imag(&fh)/
          (3 * &var^2 + 4 * (amplitude(&fph)^2+&sph^2) * &var) )
  ( acentric and &sel )

do (&pc=-amplitude(&fp)^2 * (real(&fh)^2 - imag(&fh)^2) /

Figure 18.6.6.2
Example of (*a*) a CNS module and (*b*) the corresponding module invocation. Input and output parameters are in bold. The module invocation is performed by specifying the '@' character, followed by the name of the module file and the module parameter substitutions. The ampersand (&) indicates that the particular symbol (*e.g.* '&fp') is substituted with the specified value in the invocation statement [*e.g.* 'fobs' in the case of '&fp' in (*b*)]. The module parameter substitution is performed literally, and any string of characters between the equal sign and the semicolon will be substituted.

The following example shows how the unit-cell parameters defined above (Fig. 18.6.3.1*b*) are passed into a module named 'compute_unit_cell_volume' (Fig. 18.6.6.1), which computes the volume of the unit cell from the crystal lattice parameters using well established formulae (Stout & Jensen, 1989):

$$\begin{aligned}&\texttt{@compute\_unit\_cell\_volume (cell} = \texttt{\&crystal\_lattice.unit\_cell;}\\ &\qquad\qquad\qquad\qquad \texttt{volume} = \texttt{\$cell\_volume;)}\end{aligned}\tag{18.6.6.1}$$

The parameter 'volume' is equated to the symbol '$cell_volume' upon invocation in order to return the result (the unit-cell volume) from this module. Note that the use of compound parameters to define the crystal lattice parameters (Fig. 18.6.3.1*b*) provides a convenient way to pass all required information into the module by referring to the base name of the compound

parameter (‘&crystal_lattice.unit_cell’) instead of having to specify each individual data element.

Fig. 18.6.6.2(*a*) shows another example of a CNS module: the module named ‘phase_distribution’ computes phase probability distributions using the Hendrickson & Lattman formalism (Hendrickson & Lattman, 1970; Hendrickson, 1979; Blundell & Johnson, 1976). An example for invoking the module is shown in Fig. 18.6.6.2(*b*). This module could be called from task files that need access to isomorphous phase probability distributions. It would be straightforward to change the module in order to compute different expressions for the phase probability distributions.

A large number of additional modules are available for crystallographic phasing and refinement. CNS library modules include space-group information, Gaussian atomic form factors, anomalous-scattering components, and molecular parameter and topology databases.

18.6.7. Task files

Task files consist of CNS language statements and module invocations. The CNS language permits the design and execution of nearly any numerical task in X-ray crystallographic structure determination using a minimal set of ‘hard-wired’ functions and routines. A list of the currently available crystallographic procedures and features is shown in Fig. 18.6.7.1.

Each task file is divided into two main sections: the initial parameter definition and the main body of the task file. The definition section contains definitions of all CNS parameters that are used in the main body of the task file. Modification of the main body of the file is not required, but may be done by experienced users in order to experiment with new algorithms.

Figure 18.6.7.2
Example of a typical CNS task file: a section of the top portion of the simulated-annealing refinement protocol which contains the definition of various parameters that are needed in the main body of the task file. Each parameter is indicated by a name, an equal sign and an arbitrary sequence of characters terminated by a semicolon (*e.g.* ‘a=61.76;’). The top portion of each task file also contains commands for the HTML interface embedded in comment fields (indicated by braces, {...}). The commands that can be modified by the user in the HTML form are in bold.

The definition section also contains the directives that specify specific HTML features, *e.g.* text comments (indicated by {*...*}), user-modifiable fields (indicated by {=== >}), and choice boxes (indicated by {+ choice: ...+}). Fig. 18.6.7.2 shows a portion of the ‘define’ section of a typical CNS refinement task file.

The task files produce a number of output files (*e.g.* coordinate, reflection, graphing and analysis files). Comprehensive information about input parameters and results of the task are provided in these output files. In this way, the majority of the information required to reproduce the structure determination is kept with the results. Analysis data are often given in simple columns and rows of numbers. These data files can be used for graphing, for example, by using commonly available spreadsheet programs. An HTML graphical output feature for CNS which makes use of these analysis files is planned. In addition, list files are often produced that contain a synopsis of the calculation.

18.6.8. HTML interface

The HTML graphical interface uses HTML to create a high-level menu-driven environment for CNS (Fig. 18.6.8.1). Compact and

Figure 18.6.8.1
Example of a CNS HTML form page. This particular example corresponds to the task file in Fig. 18.6.7.2.

relatively simple Common Gateway Interface (CGI) conversion scripts are available that transform a task file into a form page and the edited form page back into a task file (Fig. 18.6.8.2). These conversion scripts are written in PERL.

A comprehensive collection of task files are available for crystallographic phasing and refinement (Fig. 18.6.7.1). New task files can be created or existing ones modified in order to address problems that are not currently met by the distributed collection of task files. The HTML graphical interface thus provides a common interface for distributed and 'personal' CNS task files (Fig. 18.6.8.2).

18.6.9. Example: combined maximum-likelihood and simulated-annealing refinement

CNS has a comprehensive task file for simulated-annealing refinement of crystal structures using Cartesian (Brünger *et al.*, 1987; Brünger, 1988) or torsion-angle molecular dynamics (Rice & Brünger, 1994). This task file automatically computes cross-validated σ_A estimates, determines the weighting scheme between the X-ray refinement target function and the geometric energy function (Brünger *et al.*, 1989), refines a flat bulk solvent model (Jiang & Brünger, 1994) and an overall anisotropic B value for the model by least-squares minimization, and subsequently refines the atomic positions by simulated annealing. Options are available for specification of alternate conformations, multiple conformers (Burling & Brünger, 1994), noncrystallographic symmetry constraints and restraints (Weis *et al.*, 1990), and 'flat' solvent models (Jiang & Brünger, 1994). Available target functions include the maximum-likelihood functions MLF, MLI and MLHL (Pannu & Read, 1996; Adams *et al.*, 1997; Pannu *et al.*, 1998). The user can choose between slow cooling (Brünger *et al.*, 1990) and constant-temperature simulated annealing, and the respective rate of cooling and length of the annealing scheme. For a review of simulated annealing in X-ray crystallography, see Brünger *et al.* (1997).

During simulated-annealing refinement, the model can be significantly improved. Therefore, it becomes important to recalculate the cross-validated σ_A error estimates (Kleywegt & Brunger, 1996; Read, 1997) and the weight between the X-ray diffraction target function and the geometric energy function in the course of the refinement (Adams *et al.*, 1997). This is important for the maximum-likelihood target functions that depend on the cross-validated σ_A error estimates. In the simulated-annealing task file, the recalculation of σ_A values and subsequently the weight for the crystallographic energy term are carried out after initial energy minimization, and also after molecular-dynamics simulated annealing.

18.6.10. Conclusions

CNS is a general system for structure determination by X-ray crystallography and solution NMR. It covers the whole spectrum of methods used to solve X-ray or solution NMR structures. The multi-layer architecture allows use of the system with different levels of expertise. The HTML interface allows the novice to perform standard tasks. The interface provides a convenient means of editing complicated task files, even for the expert (Fig. 18.6.8.2). This graphical interface makes it less likely that an important parameter will be overlooked when editing the file. In addition, the graphical interface can be used with any task file, not just the standard distributed ones. HTML-based documentation and graphical output are planned in the future.

Most operations within a crystallographic algorithm are defined through modules and task files. This allows for the development of new algorithms and for existing algorithms to be precisely defined and easily modified without the need for source-code modifications.

The hierarchical structure of CNS allows extensive testing at each level. For example, once the source code and CNS basic commands have been tested, testing of the modules and task files is performed. A test suite consisting of more than a hundred test cases is frequently evaluated during CNS development in order to detect and correct programming errors. Furthermore, this suite is run on several hardware platforms in order to detect any machine-specific errors. This testing scheme makes CNS highly reliable.

Algorithms can be readily understood by inspecting the modules or task files. This self-documenting feature of the modules provides a powerful teaching tool. Users can easily interpret an algorithm and compare it with published methods in the literature. To our knowledge, CNS is the only system that enables one to define symbolically any target function for a broad range of applications, from heavy-atom phasing or molecular-replacement searches to atomic resolution refinement.

Chapter 18.7. The *TNT* refinement package

D. E. Tronrud and L. F. Ten Eyck

18.7.1. Scope and function of the package

TNT (Tronrud *et al.*, 1987) is a computer program package that optimizes the parameters of a molecular model given a set of observations and indicates the location of errors that it cannot correct. Its authors presume the principal set of observations to be the structure factors observed in a single-crystal diffraction experiment. To complement such a data set, which for most macromolecules has limitations, stereochemical restraints such as standard bond lengths and angles are also used as observations.

A molecule is parameterized as a set of atoms, each with a position in space, an isotropic B factor and an occupancy. The complete model also includes an overall scale factor, which converts the arbitrary units of the measured structure factors to e Å^{-3}, and a two-parameter model of the electron density of the bulk solvent.

Because a *TNT* model of a macromolecule does not allow anisotropic B factors, *TNT* cannot be used to finish the refinement of any structure that diffracts to high enough resolution to justify the use of these parameters. If one has a crystal that diffracts to 1.4 Å or better, the final model should probably include these parameters and *TNT* cannot be used. One may still use *TNT* in the early stages of such a refinement because one usually begins with only isotropic B's.

At the other extreme of resolution, *TNT* begins to break down with data sets limited to only about 3.5 Å data. This breakdown occurs for two reasons. First, at 3.5 Å resolution, the maps can no longer resolve β-sheet strands or α-helices. The refinement of a model against data of such low resolution requires strong restraints on dihedral angles and hydrogen bonds – tasks for which *TNT* is not well suited. Second, the errors in an initial model constructed with only 3.5 Å data are usually of such a magnitude and quality that the function minimizer in *TNT* cannot correct them.

18.7.2. Historical context

The design of *TNT* began in the late 1970s, and the first publishable models were generated by *TNT* in 1981 (Holmes & Matthews, 1981). Its design was greatly influenced by observations of the strength and weaknesses of programs then available.

The first refinement of a protein model was performed by Jensen and co-workers at the University of Washington (Watenpaugh *et al.*, 1973). This structure refinement was atypical because of the availability of high-resolution data. The techniques of pre-least-squares small-molecule refinement were simply applied to this much larger model. Since many of the calculations were performed manually, no comprehensive software package was created for distribution.

It was quickly realized that for macromolecular refinement to become common, the calculations had to be fully automated and ideal stereochemistry had to be enforced. In the late 1970s, four programs became available, all of which automated the refinement calculations, but each implemented the enforcement of stereochemistry in different ways. They were *PROLSQ* (Hendrickson & Konnert, 1980), *EREF* (Jack & Levitt, 1978), *CORELS* (Sussman *et al.*, 1977) and *FFTSF* (Agarwal, 1978). *PROLSQ* was, ultimately, the most popular.

At one end of the spectrum lay *FFTSF*. This program optimized its models to the diffraction data while completely ignoring ideal geometry. Following a number of iterations of optimizing the fit of the model to the structure factors, the geometry was idealized by running a separate program. At the other extreme was *CORELS*. It optimized its models to the diffraction data while allowing no deviations from ideal stereochemistry. The model was allowed to change only through the rotation of single bonds and the movement of rigid groups. Both approaches were frustrating to a certain extent. With *FFTSF* it was a struggle to find a model that agreed with all observations at once. With *CORELS* it was difficult to get the model to fit the density, because small and, apparently, insignificant deviations from ideality often added up after many residues to large and significant displacements, and these were forbidden. Neither approach to stereochemistry seemed very convenient, although *CORELS* was used for early-stage refinement for many years because of its exceptional radius of convergence.

Both *PROLSQ* and *EREF* enforced ideal stereochemistry and agreement with the diffraction data simultaneously. This strategy proved very convenient and generated models that satisfied their users. The two programs differed significantly in the form in which they required the ideal values be entered. *PROLSQ* required that the ideal values for both bond lengths and bond angles be entered as distances, *e.g.* an angle was defined by the distance between the two extreme atoms. *EREF* required that the standard value for an angle simply be entered as the number of degrees. Since *EREF* stored its library of standard values in the same terms as those with which people were familiar, it was much easier to enter the values.

These two programs differed in another way as well. *PROLSQ* stored ideal values for the stereochemistry of each type of residue (*e.g.* alanine, glycine *etc.*), while *EREF* parameterized the library in terms of atom types. For example, the angle formed by three atoms, the first a keto oxygen, the second a carbonyl carbon and the third an amide nitrogen, would have a particular ideal value regardless of where these three atoms occurred. In this matter, *PROLSQ* was more similar to the thought patterns of crystallographers.

18.7.3. Design principles

TNT was designed with three fundamental principles in mind. Each principle has a number of consequences that shaped the ultimate form of the package.

18.7.3.1. Refinement should be simple to run

The user should not be burdened with the choice of input parameters that they may not be qualified to choose. They also should not be forced to construct an input file that is obscure and difficult to understand. It is hard now to remember what most

Copyright © 2012 International Union of Crystallography

computer programs were like in the 1970s. Usually, the input to the program was a block of numbers and flags where the meaning of each item was defined by its line and column numbers. This block not only contained information the programmer could never anticipate, like the cell constants, but defined how the computer's memory should be allocated and obscure parameters that could only be estimated after careful reading of research papers.

TNT was one of the first programs in crystallography to have its input introduced with keywords and to allow input statements to come in any order. As an example of the difference, consider the resolution limits. Usually, a crystallographic program would have a line in its input similar to

```
99.0, 1.9,
```

One had to recognize this line amongst many as the line containing the resolution limits. (In many programs, a value of 99 was used to indicate that no lower-resolution limit was to be applied.) In *TNT* the same data would be entered as

```
RESOLUTION 1.9
```

The keyword identifies the data as the resolution limit(s). If the statement contained two numbers, they were considered the upper and lower limits of the diffraction data.

The preceding example also shows how default values can be implemented by a program much more safely with keyword-based input. In the previous scheme, if a value was ever to be changed by the user, its place had to be allocated in the input block. This often left numbers floating in the block which were almost never changed, and because they were so infrequently referred to, they were usually unrecognized by the user. It was quite possible for one of these numbers to be accidentally changed and the error unnoticed for quite some time. When the data are introduced with keywords, a data item is not mentioned if the default value is suitable.

18.7.3.2. Refinement should run quickly and use as little memory as possible

The most time-consuming calculations in refinement are the calculation of structure factors from atomic coordinates and the calculation of derivatives of the part of the residual dependent upon the diffraction data with respect to the atomic parameters. The quickest means of performing these calculations requires the use of space-group-optimized fast Fourier transforms (FFTs). The initial implementation of *TNT* used FFTs to calculate structure factors, but the much slower direct summation method to calculate the derivatives. Within a few years, Agarwal's method (Agarwal, 1978; Agarwal *et al.*, 1981) was incorporated into *TNT* and from then on all crystallographic calculations were performed with FFTs.

The FFT programs of Ten Eyck (1973, 1977) made very efficient use of computer memory. Another means of saving memory was to recognize that the code for calculating stereochemical restraints did not need to be in the memory when the crystallographic calculations were being performed and *vice versa*. There were two ways to save memory using this information. One could create a series of 'overlays' or one could break the calculation into a series of separate programs. The means for defining an overlay structure were never standardized and could not be ported from one type of computer to another and were, therefore, never attempted in *TNT*. For this reason, and a number of others mentioned here, *TNT* is not a single program but a collection of programs, each with a well defined and specialized purpose.

18.7.3.3. The source code should not require customization for each project

The need to state this goal seems remarkable in these modern times, but the truth is that most computer programs in the 1970s required specific customizations before they could be used. The simplest modifications were the definitions of the maximum number of atoms, residues, atom types *etc.* accepted by the program. These modifications are still required in Fortran77 programs because that language does not allow the dynamic allocation of memory. However, in most programs today the limits are set high enough that the standard configuration does not present a problem.

The most difficult modification required for programs like *PROLSQ* was to adapt the calculations to the space group in hand. Their authors usually included code for the space groups they were particularly interested in, leaving all others to be implemented by the user. Writing code for a new space group was often a daunting task for someone who was not an expert programmer and had no tools for testing the modifications.

It is too burdensome to require the user to understand sufficiently the internal workings of a complex calculation that they can code and debug central subroutines of a refinement program. In its initial implementation, *TNT* avoided this problem, to an extent, by performing the space-group-specific calculations in separate programs. At least the user did not need to modify an existing program. All that was required was the construction of a program that read the proper format file, performed the calculation and wrote its answer in the proper format. The user was required to supply both a program that could calculate structure factors from the model and another program that could calculate the derivative of the diffraction component of the residual function with respect to the atomic parameters of the model.

While a structure-factor program could usually be located, either by finding an existing program or by expanding the model to a lower-symmetry space group for which a program did exist, the requirement of creating a derivative program proved too great a burden. The derivation of the space-group-specific calculation, its implementation and debugging proved too difficult for almost everyone, and this design was quickly abandoned. Instead, an implementation of Agarwal's (1978) algorithm was created. In this method, the derivatives are calculated with a series of convolutions with an $F_o - F_c$ map. The calculation of the map is the only space-group-specific part of the calculation, and this was done with a separate program for calculating Fourier syntheses. Such programs were as easy to come by as structure-factor calculation programs and could be replaced by a lower-symmetry program if required.

While it is easier to find or write a program that only calculates a Fourier transform and much easier to debug one than to debug a modification to a larger and more complex program, it is still difficult. The lack of availability of programs for the space group of a crystal often prevented the use of *TNT*. Over time, programs for more space groups were written and distributed with *TNT*. Eventually, a method was developed by one of *TNT*'s authors in which FFTs could be calculated using a single program as efficiently as the original space-group-specific programs. Once this program existed, there was no longer the need for isolated structure-factor and Fourier synthesis programs. These calculations have disappeared into the heart of *TNT*, and *TNT* consists of many fewer programs today than in the past.

18.7.4. Current structure of the package

TNT presents different faces to different users. Some users simply want to run refinement; they see the shell interface. Others want to use the *TNT* programs in untraditional ways; they see the program interface. A few users want to change the basic calculations of *TNT*; they see the library interface.

The shell interface is the view of *TNT* that most people see. It is the most recent structural addition, having been added in release 5E in 1995. At this level, the restraints, weights and parameters of the model are described in the '*TNT* control file' and the user performs particular calculations by giving commands at the shell prompt. For example, refinement is performed with the 'tnt' command and maps are calculated for examination with some graphics program with the 'make_maps' command. *TNT* is supplied with about two dozen shell commands. These commands allow the running of refinement, the conversion of the model to and from *TNT*'s internal format, and the examination of the model to locate potential problem spots. The *TNT Users' Guide* describes the use of *TNT* at this level.

The program interface consists of the individual *TNT* programs along with their individual capabilities. *TNT* consists of the program *Shift*, which handles all the minimization calculations, a program for each module (restraints that fall into a common class, *e.g.* diffraction data, ideal stereochemistry and noncrystallographic symmetry) and a number of utility programs of which the most important member is the program *Convert*, which reads and writes coordinate files in many formats. The user can write shell scripts (or modify those supplied with *TNT*) to perform a great many tasks that cannot be accessed with the standard set of scripts. The *TNT Reference Manual* describes the operation of each program.

If the programs in *TNT* do not perform the calculation wanted, the source code can be modified. The source code to *TNT* is supplied with the standard distribution. In order to make the code more manageable and understandable, it is divided into half a dozen libraries. All *TNT* programs use the lowest-level library to ensure consistency of the 'look and feel' and use the basic data structures for storage of the model's parameters and the vital crystal data. To add new functionality, one can either modify an existing program, write a new program using the *TNT* libraries as a start, or write a new program from scratch ignoring the *TNT* libraries. As long as a program can read and write files of the same format as the rest of *TNT*, it will work well with *TNT*, even if it does not share any code. A library exists, but is not copyrighted, that contains subroutines to read and write the crystallographic file formats used by the rest of *TNT*.

18.7.5. Innovations first introduced in *TNT*

TNT was not only designed to be an easy-to-use tool for the refinement of macromolecular models, but also as a tool for testing new ideas in refinement. Since its source code is designed to allow easy reordering of tasks and simple modifications, a number of innovations in refinement made their first appearance in *TNT*. These features include the following.

18.7.5.1. Identifying and restraining symmetry-related contacts (1982)

Without a search for symmetry-related bad contacts, it was quite common to build atoms into the same density from two different sides of the molecule. A number of models in the Protein Data Bank contain these types of errors because neither the refinement nor the graphics programs available at that time would indicate this type of error.

18.7.5.2. The ability of a single package to perform both individual atom and rigid-body refinement (1982)

Prior to *TNT*, one often started a refinement with rigid-body refinement using *CORELS* and then switched to another program. *TNT* was the first refinement package to allow both styles of refinement. One was not required to learn about two different packages when running *TNT*.

18.7.5.3. Space-group optimized FFTs for all space groups (1989)

This innovation allowed *TNT* to run efficiently in all space groups available to macromolecular crystals.

18.7.5.4. Modelling bulk solvent scattering via local scaling (~1989)

With a simple and quick model of the scattering of the bulk solvent in the crystal (Tronrud, 1997), the low-resolution data could be used in refinement for the first time. The inclusion of these data in the calculation of maps greatly improved their appearance.

18.7.5.5. Preconditioned conjugate-gradient minimization (1990)

This method of minimization (Axelsson & Barker, 1984; Tronrud, 1992) allows the direct inclusion of the diagonal elements of the second-derivative matrix and the indirect inclusion of its off-diagonal elements. An additional benefit is that it allows both positional parameters and B factors to be optimized in each cycle. Previously, one was required to hold one class of parameter fixed while the other was optimized. It is much more efficient and simpler for the user to optimize all parameters at once. This method, because it incorporates the diagonal elements directly, produces sets of B factors that agree with the diffraction data better than those from the simple conjugate-gradient method.

18.7.5.6. Restraining stereochemistry of chemical links to symmetry-related molecules (~1992)

It is not uncommon for crystallization enhancers to be found on a special position in the crystal. In addition, cross-linking the molecules in a crystal is often done for various reasons. In both cases, the model contains chemical bonds to a molecule or atoms in another asymmetric unit of the crystal. In order for the stereochemistry of these links to be properly restrained, it must be possible to describe such a link to the refinement program.

18.7.5.7. Knowledge-based B-factor restraints (~1994)

When the resolution of the diffraction data set is less than about 2 Å, the individual B factors of a refined model are observed to vary wildly from atom to atom, even when the atoms are bonded to one another. This pattern is not reasonable if one interprets the B factor as a measure of the vibrational motion of the atom. Traditionally, one applies an additional restraint on the B factors of the model, where the ideal value for the difference in B factor for two bonded atoms is zero.

Since it is clear from examinations of higher-resolution models that the *B* factors generally increase from one side of a bond to the other (*e.g.* moving from the main chain to the end of a side chain), the traditional restraint is flawed. A restraint library was generated (Tronrud, 1996) where each bond in a residue is assigned a preferred increment in *B* factor and a confidence (standard deviation) in that increment.

18.7.5.8. Block-diagonal preconditioned conjugate-gradient minimization with pseudoinverses (1998)

With this enhancement, *TNT*'s minimizer treats the second-derivative matrix as a collection of 5×5 element blocks along its diagonal, one block for each atom. While this method improves the rate of convergence for noncrystallographic symmetry restraints, its most significant feature is that it allows the refinement of atoms located on special positions without special handling by the user.

18.7.5.9. Generalization of noncrystallographic symmetry operators to include shifts in the average B factor (1998)

It is rather common in crystals containing multiple copies of a molecule in the asymmetric unit for one or more molecules to have a higher *B* factor than the others. If the transformation that generates each copy of the molecule consists only of a rotation and translation of the positions of the atoms, the difference in *B* factors cannot be modelled. The transformations used in *TNT* now consist of a rotation, translation, a *B*-factor shift and an occupancy shift.

18.7.6. *TNT* as a research tool

TNT was intended not only as a tool for performing refinement, but as a tool for developing new ideas in refinement. While most of the latter has been done by *TNT*'s authors, several others have made good use of *TNT* in this fashion. If one has an idea to test, the overhead of writing an entire refinement package to perform that test is overwhelming. *TNT* allows modification at a number of levels, so one can choose to work at the level that allows the easiest implementation of the idea. Several examples follow.

18.7.6.1. Michael Chapman's real-space refinement package

At Florida State University, Chapman has implemented a real-space refinement package, principally intended for the refinement of virus models, using *TNT*. He was able to use *TNT*'s minimizer and stereochemical restraints unchanged along with programs he developed to implement his method. More information about this package can be found at http://www.sb.fsu.edu/~rsref.

18.7.6.2. Randy Read's maximum-likelihood function

When Navraj Pannu wanted to implement Read's maximum-likelihood refinement functions (Pannu & Read, 1996) in *TNT*, he chose not to implement it as a separate program, but modified *TNT*'s source code to create a new version of the program *Rfactor*, named *Maxfactor*.

18.7.6.3. J. P. Abrahams' likelihood-weighted noncrystallographic symmetry restraints

Abrahams (1996) conceived the idea that because some amino-acid side chains can be expected to violate the noncrystallographic symmetry (NCS) of the crystal more than others, one could develop a library of the relative strength with which each atom of each residue type would be held by the NCS restraint. He chose to determine these strengths from the average of the current agreement to the NCS of all residues of the same type. For example, if the lysine side chains do not agree well with their NCS mates, the NCS will be loosely enforced for those side chains. On the other hand, if almost all the valine side chains agree well with their mates, then the NCS will be strongly enforced for the few that do not agree well.

He chose to implement this idea by modifying the source code for the *TNT* program *NCS*. Since the calculations involved in implementing this idea are simple, the extent of the modification was not large.

18.7.6.4. The Buster refinement package

Bricogne & Irwin (1996) have developed a maximum-likelihood refinement package using *TNT*. Not only are *TNT*'s minimizer and stereochemical restraints used, but many of the calculations of the maximum-likelihood residual's derivatives are performed using *TNT* programs. While Bricogne and co-workers have not needed to modify *TNT* programs to implement their ideas, there is ongoing collaboration between them and *TNT*'s authors on the development of commands that allow access to some previously internal calculations. More information about *Buster* can be found at http://www.globalphasing.com/buster/.

18.7.7. Current status of *TNT*

TNT is no longer being actively developed at the University of Oregon. The principal use of *TNT* today is from within the *Buster* package of Global Phasing, Ltd. Over the last ten years, they have made considerable modifications to their branch of the source code which have greatly increased the radius and rate of convergence of the optimizer and expanded the scope of the distributed library of standard groups in the ideal stereochemistry library. These enhancements are only available *via* their distribution of *Buster*.

Chapter 18.8. *ARP/wARP* – automated model building and refinement

V. S. Lamzin, A. Perrakis and K. S. Wilson

A macromolecular model is an interpretation of the end result of an X-ray experiment – the *electron-density map* – and is aimed to be consistent with both the experimental data and stereochemical knowledge. At the start of the process, the crystallographer must construct an initial molecular model in the electron density. In the early days this was done literally with nuts and bolts, but was subsequently carried out with the aid of interactive modelling software. Over the last decade, this time-demanding and highly subjective step, heavily dependent on the researcher's experience, has been largely substituted by automated procedures. Automated model building programs, of which *ARP/wARP* was one of the first to be widely used, deliver high-quality molecular models rapidly and efficiently from a sufficiently good set of initial phases.

18.8.1. Refinement and model building are two parts of modelling a structure

The conventional view of crystallographic refinement of macromolecules is the optimization of the parameters of a model to fit both the experimental data and a set of *a priori* stereochemical observations. The user provides a model, whose parameters are allowed to vary during a set minimization cycles based on least-squares or maximum-likelihood protocols. In conventional refinement procedures, the presence of the atoms is fixed, *i.e.* there is no addition or removal of parts of the model. As a result, users are often faced with a situation where several atoms in the model lie in one place, while the density maps suggest an entirely different location. The minimization procedures themselves are unable to make such major modifications to the model. Manual intervention, consisting of moving atoms to a more appropriate place using molecular graphics, density maps and geometrical assumptions, is required to enable improvement of the model to proceed.

ARP/wARP has built on two innovative concepts (Lamzin & Wilson, 1993, 1997; Perrakis *et al.*, 1999).

(1) It challenged the previous separation of model building and refinement software by taking a more general view of the underlying phase optimization through coordinate manipulation and by incorporating the data-driven extension of the macromolecular model as part of an integrated approach. Addition and/or deletion of atoms (*model update*) and complete re-evaluation of the model with an aim of creating a modified one that better describes the electron density (*model reconstruction*) are essential components. *Atom removal* is primarily based on the interpolated likelihood-weighted electron density at an atomic centre and the agreement of the atomic density distribution with a target shape. *Atom addition* uses the difference likelihood-gradient synthesis. The selection is based on map grid points rather than peaks, as the latter are often poorly defined and may overlap with neighbouring peaks or existing atoms, especially if the resolution and phases are poor.

(2) *ARP/wARP* also challenged the view that throughout the structure-determination process a macromolecular model should always consist of a known set of atoms of an appropriate type, connected by bonds according to the known stereochemistry. The concept of a *hybrid model*, described in detail in Section 18.8.2, was introduced where a partial macromolecular model is deduced from the interpretable part of the electron density, while the remaining regions are modelled with free atoms that have undefined chemical identity and no bonds. This placed structure solution on a more unified foundation and enabled automation in linking the entire procedure.

The hybrid model undergoes optimization with the *REFMAC* engine (Murshudov *et al.*, 1997), where the model parameters are adjusted to fit better the experimental data and *a priori* stereochemical expectations. If the quality of the hybrid model is sufficiently high, the phases improve overall and a more complete model can be constructed from the enhanced electron density. The hybrid model iteratively evolves (precisely what is needed to escape from a local minimum of the optimization landscape) and should converge on the final macromolecular model, with the remaining free atoms approximating the surrounding solvent structure. The fundamental limitations of *ARP/wARP* as well as related macromolecular structure determination approaches are the amount of the available X-ray data (resolution) and the quality of the initial phase estimates.

18.8.2. Free-atom and hybrid models

A crystallographic electron-density map is always sampled on a regular grid. The goal of macromolecular model building is to condense the electron-density information to a molecular model. *ARP/wARP* entirely follows the paradigm of syntactic model construction starting from free atoms, through candidate Cα atoms, peptide and dipeptide units and chain fragments to sequence docking and side-chain building. As a first step, *ARP/wARP* condenses the map information to a set of *free atoms* (Agarwal & Isaacs, 1977), as described by Lamzin & Wilson (1997), that have undefined chemical identity: these atoms are chosen to represent the electron density as accurately as possible, but resemble a protein-like model in their distribution. The free atoms can be complemented by an initial (partial) protein model if available. To build a free-atom model, only an estimate of the molecular weight of the protein is required, without any sequence information. For example, for protein-model building a map covering a crystallographic asymmetric unit on a fine grid of about 0.33 Å is constructed. The model is gradually expanded from a seed by the stepwise addition of free atoms in lower electron density and at bonding distances from existing atoms. The procedure continues until the number of atoms is about $3n$, where n is the number expected. This number is then reduced to about n + 10% atoms by removing atoms in the lowest density. This procedure has the advantage that it places the free atoms at protein-like distances while covering the whole volume of the protein.

Such a free-atom model can describe almost every feature of an electron-density map, but this interpretation rarely provides a

Copyright © 2012 International Union of Crystallography

conventional picture of a protein. Nevertheless, information from parts of the improved map and the free-atom model can be used to recognize automatically real elements of protein structure by applying the model-reconstruction algorithms, so that at least a partial atomic protein model can be built. During iterative model building and refinement some free atoms gain chemical identity, whereas others remain free. Combination of this partial protein model with a free-atom set (a *hybrid* model) allows a considerably better description of the current map. The protein model provides additional information (in the form of stereochemical restraints), while prominent features in the electron density (unaccounted for by the current model) are described by free atoms. Importantly, use of the atomic positions in the hybrid model, rather than map grid points, as guides for model building in the electron-density maps allows the implementation of computationally more efficient algorithms.

18.8.3. *ARP/wARP* applications

Although *ARP/wARP* started life as a tool to build proteins, it now provides a wider spectrum of functionalities. As of the software version 7.1 (2009) *ARP/wARP* tackles several tasks in macromolecular crystallography:

(i) iterative protein-model building including a decision-making control module;
(ii) fast construction of the secondary structure of a protein;
(iii) sequence docking and side-chain building and refinement;
(iv) building flexible loops in alternate conformations;
(v) building DNA or RNA polynucleotide fragments;
(vi) fully automated placement of ligands, including a choice of the best-fitting ligand from a 'cocktail'; and
(vii) locating ordered water molecules.

ARP/wARP protocols are computationally efficient so that the time required is typically of the order of a few minutes on modern workstations, although iterative protein-model building may take a few hours. *ARP/wARP* applications are briefly described below, but for a detailed overview a reader is referred to Langer *et al.* (2008) or the literature cited hereafter.

18.8.3.1. Iterative protein-model building

If initial experimental phase information is available, the hybrid models are used as the main tool for obtaining as full a protein model as possible from the map calculated with the initial phases. A molecular-replacement solution can be directly used as an initial hybrid model. Given the information contained in the hybrid model in the traditional form of stereochemical restraints, refinement can work more efficiently, new improved phases can be obtained and a more accurate and complete protein model can be constructed. The new hybrid model is re-input to the refinement and these steps are iterated so that improved phases result in the construction of longer fragments of the protein chains. An almost complete protein model can often be obtained in a fully automated way (Fig. 18.8.3.1).

Automatic density-map interpretation for proteins is based on the location of the atoms in the current model and consists of several steps. Firstly, each pair of atoms in the free-atom model located at a distance of 3.8 ± 1.0 Å is assigned a potential peptide connection. The method utilizes the fact that all residues that comprise a protein, with the exception of *cis*-peptides, have chemically and structurally identical main-chain fragments with a highly characteristic, close-to-planar shape: the Cα—C—O—N—Cα *trans*-peptide units.

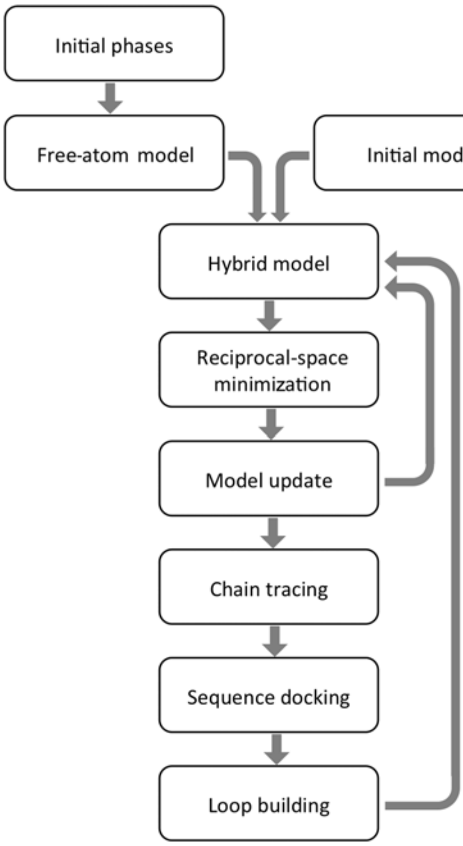

Figure 18.8.3.1
A flow chart of the iterative building of a protein structure with *ARP/wARP*.

The problem of searching for possible peptide units and their connections thus becomes straightforward. Peptide recognition between potential Cα pairs takes place by matching the electron density that surrounds each potential pair (Lamzin & Wilson, 1997) to that pre-computed for true Cα pairs from known structures. The peptide search uses density shapes sampled at 915 points, which account not only for the resolution of the X-ray data, but also for the fall-off in the diffraction intensity with resolution (the Wilson *B* factor). The important constraint here is that proteins are composed of linear non-branching polypeptide chains, allowing sets of connected peptides to be obtained from an initial list of all possible tracings. A limited depth-first graph-search algorithm is used for the assembly of peptides into linear polypeptide chain fragments for protein chain tracing (Morris *et al.*, 2002). Selection of the direction of a chain path is based on the electron density and observed backbone conformations. However, the set of peptide units and the list of how they are interconnected do not allow unambiguous tracing of a full-length chain for most structures.

The crucial bottleneck in automatically reconstructing a protein model from electron-density maps is achieving an initial trace of the polypeptide chain, typically approximated by many or hopefully only a few polypeptide fragments. Iteratively, these fragments should be made longer, their number should decrease and possible tracing errors, arising from poor starting phases, are eliminated. Following that, the fragments have to be placed in sequence, side chains built and gaps between the fragments that have been docked in sequence must be filled.

The complexity of the chain tracing can be illustrated as follows. Let us assume an example with 10 000 trial peptide units, where each free atom has, on average, two incoming and two outgoing peptides; this is typical for a good electron-density map of a 100 kDa (1000 residue) protein. Assuming that both ends of the chain are known and that it is possible to connect all the points regardless of the chosen route, then one is faced with the problem of choosing the best chain out of 2^{999} candidates. Screening all possible pairs of chain ends increases this number even further. Clearly, an exhaustive search is not computationally feasible. In practice, the situation is even more complex, since not all trial peptides are necessarily correctly identified in the first iteration, and some may be missing – analogous to the correctness or incorrectness of the atomic positions mentioned above. *ARP/wARP* uses a number of algorithmic shortcuts and condenses a vast amount of information, *e.g.* for the above example from 10^6 grid points of the map, through 10^4 free atoms, 2×10^4 peptide candidates, 5×10^4 dipeptide connections, down to 2×10^3 possible peptides and finally into a model with 10^4 atoms. Protein residues are differentiated only as glycine, alanine, serine and valine, and complete side chains are not built at this stage.

For every residue in the traced polypeptide fragments, a side-chain type is assigned with an empirical probability, using either connectivity criteria between free atoms and the α-carbon position, or rotamer conformations and their correlation to the density map (Cohen *et al.*, 2004). Given these guesses for the side chains and the known primary sequence, each polypeptide fragment is docked into sequence. Following this assignment, side chains are built in the best rotamer configuration.

After sequence docking, the missing parts of the model, typically extended and poorly ordered surface loops, can be identified. Using a distribution of five-Cα fragments derived from known structures, a number of structurally possible conformations are constructed. The procedure follows a pattern-recognition-based approach, where potential Cα candidates are looked for in non-negative density, followed by the construction of peptide planes and validation of dipeptide geometry using the Ramachandran plot. The loops are then scored based on the density and the best fitting ones are selected (Joosten *et al.*, 2008).

In essence, *ARP/wARP* improves the convergence properties of map interpretation during the course of protein building and refinement in the form of partial stereochemical assignments of the model. The landscape of the objective function used in refinement thus undergoes topological changes, which minimize model bias and favour convergence to a global minimum. Taken together, the probabilistic identification of the peptide units, the naturally high conformational flexibility of the connections of the peptide units, and the limited quality of the X-ray data and/or phases introduce large enough errors to cause density breaks in the middle of the chains or result in density overlaps. The result of such a tracing is usually a set of several main-chain fragments. The less accurate the starting maps (*i.e.* initial phases) and the lower the resolution and quality of the X-ray data, the more breaks there will be in the tracing and the higher the number of peptide units that will be difficult to identify.

18.8.3.2. Recognition of secondary structural elements

At a resolution of 3.0 Å and worse, where electron-density maps lack atomic features, *ARP/wARP* uses a different algorithm to build an initial model. Instead of free atoms, sparse map grid points with ~1 Å spacing are selected as potential Cα atoms on the basis of their density. A statistical pattern-classification approach based on supervised learning is applied. Numerical features corresponding to the distances and angles within building units larger than single peptides that have well defined patterns in electron-density maps are exploited using a nonlinear discriminant as the classification engine. This parameterizes the distribution of the feature values by a suitable hyperbody (*e.g.* an ellipsoid) and takes the body isosurfaces as decision boundaries. The discriminant threshold is set so as to minimize the number of false negatives in the net classification result. The process scores and filters fragments, and then assembles longer fragments iteratively. These undergo the same filtering with an adapted discriminant function, in a hierarchical order to make this procedure computationally inexpensive. The result is a set of Cα fragments that conform to known α-helical or β-stranded conformations. Finally, peptide backbone and Cβ atoms are added, the chain fragments are refined in real space, and the most probable chain direction is selected.

When the protein structure is (nearly) complete, smaller compounds (polynucleotides, ligands, cofactors and solvent) bound to the protein can be modelled in the difference electron-density map as outlined below.

18.8.3.3. Building polynucleotide fragments

Compared to proteins, crystals of nucleic acids in complex with proteins tend to have a less ordered crystalline arrangement, diffract less well and yield structures that exhibit higher atomic displacement parameters. Like the search for the secondary structural elements, *ARP/wARP* uses sparse grid points of the electron density and identifies candidate planar bases and phosphate groups that are expected to scatter strongly and be easier to discriminate (Hattne & Lamzin, 2008). The numerical algorithm is based on the use of third-order moment invariants. The method does not rely on any particular spatial arrangement of nucleotides and allows for wide structural variance in single- or double-stranded nucleic acids, especially in RNA. The problem of polynucleotide chain tracing is formulated in a manner analogous to that for proteins, but instead of peptides the search is carried out for phosphate–sugar–phosphate groups using pre-computed 915-point density shapes. The nucleotide chains are assembled like those of proteins with the difference that tracing a protein main chain accounts for two conformational degrees of freedom per residue, while a nucleotide unit has five.

18.8.3.4. Building bound ligands

To facilitate ligand building, all regions of difference density that have approximately the same volume as the ligand are identified. Subsequently, several numeric features of the density region and its sparse representation are used to produce an ensemble of putative ligand structures to best fit the local density. All ligand model candidates are refined in real space to fit the density shape and the single best model is chosen (Evrard *et al.*, 2007). A technique that compares the shapes of difference-electron-density blobs with the shape of the ligand to be built is used to distinguish compounds from a list (cocktail) of ligand candidates. The ligand that fits best is selected for further construction of the ensemble and subsequent restrained refinement.

18.8.3.5. Solvent building

In this application, the protein model (together with bound metals, ligands or nucleic acids) is not rebuilt during refinement. Instead, only the solvent structure is continuously updated. Since ordered solvent in a typical crystal structure comprises about

10% of the model, improvement of solvent indirectly improves the density corresponding to the protein part.

18.8.4. Iterations

Building protein chains or solvent with *ARP/wARP* proceeds in an iterative fashion. When the quality of the (partially built) model is sufficiently high, the phases improve overall and result in an enhanced electron density where a more accurate and more complete model may be built. An important component within iterations is the model update, described above, where parts of the existing model located in weak density are removed and new atoms added where the density acquires pronounced features. The iterative approach can also be extended to the building of ligands and nucleic acids.

18.8.5. Applicability and requirements

Model building with *ARP/wARP* is dependent on the resolution and quality of the X-ray data. Highly complete and accurate protein models are obtained at a resolution of 2.7 Å or higher provided that reasonable starting phase estimates are available. Success has been reported at lower resolution, but it is strongly dependent on the initial phase quality. Recent advances in refinement using experimental phasing information (Skubák *et al.*, 2009) proved essential for successful automated model building in a number of difficult test cases. The resolution of the X-ray data places similar limitations on *ARP/wARP* ligand building. Building secondary structural elements does not use free atoms and is applicable at a resolution of as low as 4.5 Å. We note that the quoted resolution limits relate to the current version of the software and are likely to change in the future.

Chapter 18.9. Macromolecular applications of *SHELX*

G. M. Sheldrick

18.9.1. Introduction

The first version of *SHELX* was written around 1970 for the solution and refinement of organic and inorganic structures. Since then, most routine structure determinations published in parts B, C and E of *Acta Crystallographica* have made use of at least one of the *SHELX* programs. However, this account will be restricted to the experimental phasing and refinement of macromolecular structures; details of other applications may be found in Sheldrick (2008). The *SHELX* programs are available as open source and as precompiled executables for common computer systems. They are written in a simple Fortran subset with a strict 'zero dependency' philosophy: the stand-alone binaries use no extra programs, libraries, data files or environmental variables *etc.*, which makes them easy to install and use. The programs are designed to be called from a command line and for incorporation into GUIs (graphical user interfaces); for example, experimental phasing with *SHELXC*, *SHELXD* and *SHELXE* may be performed *inter alia via* the *HKL2MAP* (Pape & Schneider, 2004), *CCP4i* (Potterton *et al.*, 2003), *AUTOSHARP* (Vonrhein *et al.*, 2007), *HKL-3000* (Minor *et al.*, 2006) and *CRANK* (Ness *et al.*, 2004) GUIs and the *AUTORICKSHAW* (Panjikar *et al.*, 2005) and *ARCIMBOLDO* (Rodriguez *et al.*, 2009) servers. The *SHELX* programs are general for all space groups in conventional settings or otherwise and make extensive use of default settings to keep user input and confusion to a minimum. Particular care has been taken to test the programs thoroughly on as many computer systems and crystallographic problems as possible before they were released, a process that often required several years!

18.9.2. Experimental phasing with *SHELXC/D/E*

Experimental phasing of macromolecules usually requires the presence of a relatively small number of atoms with significantly greater real or anomalous scattering power than the majority of atoms in the structure. These atoms can be *e.g.* metal or sulfur atoms already present in a native protein, heavy metals or halides introduced by soaking, or selenium incorporated by replacing methionine by selenomethionine using a suitable expression system. It is first necessary to locate the positions of these atoms in the unit cell, often using direct or Patterson methods and programs originally designed to solve small-molecule structures. These atoms (referred to as the substructure) are used to estimate starting phases for the complete macromolecule, which are then refined by modifying the electron density so that it corresponds better to the expected density whilst remaining consistent with the experimental native intensity data. In the *SHELX* system (Sheldrick, 2008, 2010), the program *SHELXC* is used to analyse and process the reflection data, and write the files that are then read by *SHELXD* for location of the substructure and *SHELXE* for derivation of the starting phases and density modification. In these programs, the experimental phasing is reduced to its absolute essentials, with the aim of obtaining an interpretable electron-density map quickly and reliably, rather than finding the most accurate phases. This requires some severe simplifications, for example the assumption that there is only one type of substructure atom present, although in practice a mixture of elements rarely causes problems. The approach has the advantage of producing robust, fast and simple to use programs but is restricted to experimental phasing by MAD (multi-wavelength anomalous dispersion), SAD (single-wavelength anomalous dispersion), SIR (single isomorphous replacement), SIRAS (combined SAD and SIR) and RIP (phasing based on radiation-induced changes in the structure) methods.

18.9.2.1. Substructure location with SHELXD

The program *SHELXD* (Usón & Sheldrick, 1999; Schneider & Sheldrick, 2002; Sheldrick, 2008: see also Chapter 16.1 in this volume) was originally designed for the *ab initio* solution of macromolecular structures from atomic resolution native data alone, but has proved very useful for substructure solution at much lower resolution. The dual-space approach of *SHELXD* was inspired by the *Shake and Bake* philosophy of Miller *et al.* (1993, 1994) but differs in many details, in particular in the use it makes of the Patterson function, which proves very effective in substructure solution. An advantage of the Patterson function is that it provides a good noise filter for the ΔF or F_A data: negative regions of the Patterson function can simply be ignored. On the other hand, the direct-methods approach is efficient at handling a large number of sites, whereas the number of Patterson peaks to analyse increases with the square of the number of atoms. Thus, for reasons of efficiency, the Patterson function is employed at two stages in *SHELXD*: at the beginning to obtain pseudo-random starting atom positions that are consistent with the Patterson (usually referred to as Patterson seeding) and to calculate a triangular table in which the off-diagonal elements are a Patterson minimum function for vectors between one potential atom and a second atom including all its symmetry equivalents (Schneider & Sheldrick, 2002). This table, which also showed the minimum distances between atoms taking symmetry into account, was very useful for recognizing NCS (noncrystallographic symmetry) in substructures obtained from borderline data, but proved difficult to automate and so has remained a 'crossword table' for the amusement of experts (it is still written by *SHELXD* to the listing file). Similarly, a figure of merit PATFOM calculated by *SHELXD* on the basis of this table has proved less useful than expected in practice, because the values are not on an absolute scale; they tend to be much higher for small substructures.

18.9.2.2. Practical considerations for substructure solution

The resolution to which the data have to be truncated is usually the most critical decision for substructure solution. When the anomalous signal is weak, using data out to the diffraction limit introduces noise and may well not lead to a solution. On the other hand, truncating the resolution too strongly leads to less precise atomic positions and may result in weaker sites being missed. The mean ratio of the average absolute anomalous difference to its

Copyright © 2012 International Union of Crystallography

estimated standard deviation can be used as a guide as to where to truncate the data, but this requires good estimates of the standard deviations of the measured intensities. A better guide is the correlation coefficient between the signed anomalous differences for the different wavelengths in a MAD experiment (Schneider & Sheldrick, 2002), or for two different crystals in a SAD experiment. In a sulfur SAD experiment, the two sulfur atoms in a disulfide bridge behave as a single 'super-sulfur' atom at resolutions less than about 2.1 Å. Although this is no impediment to finding them with *SHELXD*, their phasing power is significantly enhanced if they are resolved into their two component sulfur atoms using the DSUL instruction in *SHELXD*.

To allow for possible variations in occupancy or displacement parameters (B values) and the presence of different types of marker atoms, it has proved useful to refine the occupancies in the last two dual-space cycles. A sharp fall-off in the refined occupancy between the last true site and the first noise peak is also a useful test for a good solution, but cannot be used for halide soaks, for which a continuous range of occupancies is usually found; usually the peak list is truncated at about 0.2 times the occupancy of the highest peak, because experience indicates that weaker peaks may well be noise. The correlation coefficient (CC) between the observed and calculated E values usually enables correct solutions to be identified unambiguously, and the value of CC(weak), the correlation coefficient based on the reflections not used in the dual-space recycling, is also a good check. It is like a free R value, but is not quite independent because all the data are used in the occupancy refinement.

For large substructures, it is important not to terminate the search after too small a number of trials. Often, a much better solution is found if more trials are performed. Several structures have given only one correct solution in 10 000 trials (and in one case only one in 1.6 million trials!). Since the default *SHELXD* action is to start each job with a different random number seed, one efficient approach is to run several copies in parallel, *e.g.* one per CPU (Fu *et al.*, 2007). This may conveniently be combined with different values for the resolution cutoff.

18.9.2.3. SHELXE: density modification

The density modification in *SHELXE* does not make use of solvent flattening or histogram matching. Instead, the *sphere of influence algorithm* (Sheldrick, 2002) is used to provide an indication as to how likely it is that each individual voxel (volume element) in the map corresponds to a true atomic site. The variance V of the density on a spherical surface of radius 2.42 Å is calculated for each voxel in the map. The use of a spherical surface rather than a spherical volume was intended to save time and add a little chemical information (2.42 Å is a typical 1,3 distance in proteins and DNA). V gives an indication of the probability that a voxel corresponds to a true atomic position. Voxels with low V are *flipped* ($\rho' = -\rho\gamma$ where γ is usually set to 1.0). For voxels with high V, ρ is replaced either by $\{\rho^4/[\upsilon^2\sigma^2(\rho) + \rho^2]\}^{1/2}$ [where ν is usually 0.5 and $\sigma^2(\rho)$ is the variance of the density ρ over the whole cell] if positive or by zero if negative. An empirical weighting scheme for phase recombination is used to combat model bias. The variance over all voxels in the asymmetric unit of the individual variances V, output by the program as the 'contrast', is a good indication of which marker atom enantiomorph is correct; it is almost invariably higher for the correct choice, especially after 5–10 density-modification cycles.

A further simple and effective algorithm to improve the phases of the experimentally measured reflections is to extrapolate the data and phases to a higher resolution than was actually accessible: the *free lunch algorithm* (Caliandro *et al.*, 2005; Yao *et al.*, 2006). This has also been implemented in *SHELXE* (Usón *et al.*, 2007). This algorithm is effective when data have been measured to a resolution of 2.0 Å or better, and can lead to improvements in the mean phase error of the measured reflections of between 5 and 30°.

18.9.2.4. Integrated density modification and autotracing

A relatively fast iterative autotracing algorithm has been incorporated into the density modification in *SHELXE* (Sheldrick, 2010). It is primarily designed to get a toehold in maps with very poor starting phases, *e.g.* with a mean phase error greater than 60°. The tracing proceeds as follows:

(i) Find potential α-helices in the density and try to extend them at both ends. Then find other potential tripeptides and try to extend them at both ends in the same way.
(ii) Add traces obtained by applying NCS operations derived from the heavy-atom positions, provided that they fit the density well.
(iii) Tidy up and splice the traces as required.
(iv) Use the traced residues to estimate phases and combine these with the initial phase information using σ_A weights (Read, 1986), then restart the density modification. The refinement of one B value per residue provides a further opportunity to suppress wrongly traced residues.

Crystallographic symmetry is taken into account at all stages, and the backbone traces are selected with the help of the following criteria:

(i) The modified density ρ' should be high at the atomic sites and low at the dummy-atom positions (generated at sites where no atom should be found).
(ii) The chains must be long enough (in general at least seven amino acids); longer chains are given a higher weight.
(iii) A few Ramachandran outliers can be tolerated, *e.g.* for glycines, but in general the φ and ψ angle pairs should lie in the well populated regions of the Ramachandran diagram.
(iv) There should be a well defined secondary structure (*i.e.* φ/ψ pairs should tend to be similar for consecutive residues).
(v) On average, there should be significant positive density 2.9 Å from N in the N→H direction (to a hydrogen-bond acceptor). This takes into account that the large majority of main-chain NH groups in proteins take part in hydrogen bonds with oxygen or other electronegative atoms.

At the time of writing, the autotracing version of *SHELXE* is still at the β-test stage, but the results are encouraging. The ability to trace the structure in a way that is consistent with the above criteria is a very good indicator as to whether the structure has been solved. Two internet servers for experimental phasing that use this version effectively are *AUTORICKSHAW* (Panjikar *et al.*, 2005) and *ARCIMBOLDO* (Rodríguez *et al.*, 2009). In the latter, Usón and co-workers use this ability to trace maps with large initial phase errors, and so to find a few correct solutions in a large number of trials generated by molecular-replacement searches for short α-helices, as part of a procedure for the *ab initio* solution of protein structures with data down to 2.0 Å resolution (see Chapter 16.1).

18.9.3. Macromolecular refinement using *SHELXL*

SHELXL is a very general refinement program and is equally suitable for the refinement of minerals, organometallic structures, oligonucleotides or proteins (or any mixture thereof) against X-ray or neutron single- (or twinned!) crystal data. It has even been used with diffraction data from powders, fibres and two-dimensional crystals. The price of this generality is that it is somewhat slower than programs specifically written only for protein structure refinement. Structure factors are calculated by summation rather than by a fast Fourier transform; this is more precise but slower. Any protein- (or DNA-)specific information must be input to *SHELXL* by the user in the form of refinement restraints *etc.* Refinement of macromolecules using *SHELXL* has been discussed by Sheldrick & Schneider (1997).

Least-squares (LS) refinement has the advantage that it provides proper estimates of the standard deviations in all refined and derived parameters. However, at low data-to-parameter ratios, maximum likelihood (ML) refinement is better at avoiding overfitting and is less sensitive to reflection outliers. For this reason, ML refinement, as implemented in, for example, *REFMAC* (Murshudov *et al.*, 1997), *PHENIX_REFINE* (Adams *et al.*, 2002) or *BUSTER-TNT* (Blanc *et al.*, 2004), is recommended when the data-to-parameter ratio falls below about 5. ML refinement also enables experimental phase information to be incorporated (Pannu *et al.*, 1998).

18.9.3.1. *Constraints and restraints*

In refining macromolecular structures, it is almost always necessary to supplement the diffraction data with chemical information in the form of *restraints*. A typical restraint is the condition that a bond length should approximate to a target value with a given estimated standard deviation; restraints are treated as extra experimental data items. Even if the crystal diffracts to 1.0 Å, there may well be poorly defined disordered regions for which restraints are essential to obtain a chemically sensible model (the same can be true of small molecules too!). *SHELXL* is generally not suitable for refinements at resolutions lower than about 2.0 Å because it cannot currently handle general potential-energy functions, *e.g.* for torsion angles or hydrogen bonds; if noncrystallographic symmetry restraints can be employed, this limit can be relaxed a little. Unimodal restraints, such as target distances, are less likely to result in local minima than are multimodal restraints, such as torsion angles; multimodal functions are better used as validation criteria. It is fortunate that validation programs, such as *MolProbity* (Davis *et al.*, 2007), make good use of multimodal functions such as torsion angles and hydrogen-bonding patterns that are not employed as restraints in *SHELXL* refinements.

For some purposes (*e.g.* riding hydrogen atoms, rigid-group refinement, or occupancies of atoms in disordered side chains), *constraints*, exact conditions that lead to a reduction in the number of variable parameters, may be more appropriate than restraints; *SHELXL* allows such constraints and restraints to be mixed freely. Riding hydrogen atoms are defined such that the C—H vector remains constant in magnitude and direction, but the carbon atom is free to move; the same shifts are applied to both atoms, and both atoms contribute to the least-squares derivative sums. This model may be combined with anti-bumping restraints that involve hydrogen atoms, which helps to avoid unfavourable side-chain conformations. *SHELXL* also provides, *e.g.*, methyl groups that can rotate about their local threefold axes; the initial torsion angle may be found using a difference-electron-density synthesis calculated around the circle of possible hydrogen-atom positions.

18.9.3.2. *Least-squares refinement algebra*

The original *SHELX* refinement algorithms were modelled closely on those described by Cruickshank (1970). For macromolecular refinement, an alternative to (blocked) full-matrix refinement is provided by the conjugate-gradient solution of the least-squares normal equations as described by Hendrickson & Konnert (1980), including preconditioning of the normal matrix that enables positional and displacement parameters to be refined in the same cycle. The structure-factor derivatives contribute only to the diagonal elements of the normal matrix, but all restraints contribute fully to both the diagonal and non-diagonal elements, although neither the Jacobian nor the normal matrix itself are ever generated by *SHELXL*. The parameter shifts are modified by comparison with those in the previous cycle to accelerate convergence whilst reducing oscillations. Thus, a larger shift is applied to a parameter when the current shift is similar to the previous shift, and a smaller shift is applied when the current and previous shifts have opposite signs. The STIR instruction enables the resolution to be extended stepwise during the refinement, thereby increasing the radius of convergence, and is recommended for the first refinement job starting from an unrefined model. It can also be used to reduce memory effects if the $R_{\rm free}$ reflection set has been modified.

SHELXL refines against F^2 rather than F, which enables all data to be used in the refinement with weights that include contributions from the experimental uncertainties, rather than having to reject F values below a preset threshold; there is a choice of appropriate weighting schemes. Provided that reasonable estimates of $\sigma(F^2)$ are available, this enables more experimental information to be employed in the refinement; it also allows refinement against data from twinned crystals.

18.9.3.3. *Full-matrix estimates of standard uncertainties*

Inversion of the full normal matrix (or of large matrix blocks, *e.g.* for all positional parameters) enables the precision of individual parameters to be estimated (Rollett, 1970), either with or without the inclusion of the restraints in the matrix. The standard uncertainties in dependent quantities (*e.g.* torsion angles or distances from mean planes) are calculated in *SHELXL* using the full least-squares correlation matrix. These standard uncertainties reflect the data-to-parameter ratio, *i.e.* the resolution and completeness of the data and the percentage of solvent, and the quality of the agreement between the observed and calculated F^2 values (and the agreement of restrained quantities with their target values when restraints are included).

Full-matrix refinement is also useful (together with the stepwise increase of resolution STIR) when domains are refined as rigid groups in the early stages of refinement (*e.g.* after structure solution by molecular replacement), since the total number of parameters is small and the correlation between parameters may be large.

18.9.3.4. *Refinement of anisotropic displacement parameters*

The motion of macromolecules is clearly anisotropic, but the data-to-parameter ratio rarely permits the refinement of the six independent anisotropic displacement parameters (ADPs) per atom; even for small molecules and data to atomic resolution, the anisotropic refinement of disordered regions requires the use of restraints. *SHELXL* employs three types of ADP restraint

(Sheldrick 1993; Sheldrick & Schneider, 1997). The *rigid bond restraint*, first suggested by Rollett (1970), assumes that the components of the ADPs of two atoms connected *via* one (or two) chemical bonds are equal within a specified standard deviation. This has been shown to hold accurately (Hirshfeld, 1976; Trueblood & Dunitz, 1983) for precise structures of small molecules, so it can be applied as a *hard* restraint with small estimated standard deviation. The *similar ADP restraint* assumes that atoms that are spatially close (but not necessarily bonded, because they may be different components of a disordered group) have similar U^{ij} components. An *approximately isotropic restraint* is useful for isolated solvent molecules. These two restraints are only approximate and so should be applied with low weights, *i.e.* high estimated standard deviations.

The transition from isotropic to anisotropic roughly doubles the number of parameters and almost always results in an appreciable reduction in the R factor. However, this represents an improvement in the model only when it is accompanied by a significant reduction in the free R factor (Brünger, 1992). Since the free R factor is itself subject to uncertainty because of the small sample used, a drop of at least 1% is needed to justify anisotropic refinement. The resulting displacement ellipsoids should make chemical sense and not be '*non-positive-definite*'!

18.9.3.5. Similar geometry and NCS restraints

When there are several identical chemical moieties in the asymmetric unit, a very effective restraint is to assume that the chemically equivalent 1,2 and 1,3 distances are the same, but unknown. This technique is easy to apply using *SHELXL* and is often employed for small-molecule structures and, in particular, for oligosaccharides. Similarly, the P—O bond lengths and six O···O distances in all phosphate anions can be assumed to be the same (but without a target value), *i.e.* it is assumed that the whole crystal is at the same pH. Local noncrystallographic symmetry (NCS) restraints (Usón *et al.*, 1999) may be applied to restrain corresponding 1,4 distances and isotropic displacement parameters to be the same when there are several identical macromolecular domains in the asymmetric unit; usually, the 1,2 and 1,3 distances are restrained to standard values in such cases and so do not require NCS restraints. Such *local NCS restraints* are more flexible than *global NCS constraints* and – unlike the latter – do not require the specification of a transformation matrix and mask.

18.9.3.6. Modelling disorder and solvent

There are many ways of modelling disorder using *SHELXL*, but for macromolecules the most convenient is to retain the same atom and residue names for the two or more components and assign a different 'part number' (analogous to the PDB alternative site flag) to each component. With this technique, no change is required to the input restraints *etc.* Atoms in the same component will normally have a common occupancy that is assigned to a 'free variable'. If there are only two components, the sum of their occupancies can be constrained to be unity; if there are more than two components, the sum of their free variables may be restrained to be unity. Since any linear restraint may be applied to the free variables, they are very flexible, *e.g.* for modelling complicated disorder. By restraining distances to be equal to a free variable, a standard deviation of the mean distance may be calculated rigorously using full-matrix least-squares algebra.

Babinet's principle is used to define a bulk solvent model with two refinable parameters (Moews & Kretsinger, 1975), and global anisotropic scaling (Usón *et al.*, 1999) may be applied using a parameterization proposed by Parkin *et al.* (1995). An auxiliary program, *SHELXWAT*, allows automatic water divining by iterative least-squares refinement, rejection of waters with high displacement parameters, difference-electron-density calculation, and a peak search for potential water molecules that make at least one good hydrogen bond and no bad contacts; this is a simplified version of the *ARP* procedure of Lamzin & Wilson (1993).

18.9.3.7. Twinned crystals

SHELXL provides facilities for refining against data from merohedral, pseudo-merohedral and non-merohedral twins (Herbst-Irmer & Sheldrick, 1998). Refinement against data from merohedrally twinned crystals is particularly straightforward, requiring only the twin law (a 3 × 3 matrix) and starting values for the volume fractions of the twin components. Failure to recognize such twinning not only results in high R factors and poor quality maps, it can also lead to incorrect biochemical conclusions (Luecke *et al.*, 1998). Twinning can often be detected by statistical tests (Yeates & Fam, 1999), and it is probably much more widespread in macromolecular crystals than is generally appreciated!

18.9.4. *SHELXPRO* – protein interface to *SHELX*

The *SHELX* system includes several auxiliary programs, the most important of which for macromolecular users is *SHELXPRO*. *SHELXPRO* provides an interface between *SHELXL* and other programs commonly used by protein crystallographers. Often, *SHELXL* will be used only for the final stages of refinement, in which case *SHELXPRO* is used to generate the *name.ins* file from a PDB format file, inserting the necessary restraints and other instructions. A corresponding .hkl file may be generated using the programs *XPREP* (Bruker AXS, Madison, Wisconsin) or *MTZ2HKL* (Grune, 2008). *SHELXPRO* is also used to prepare the *name.ins* file for a new refinement job based on the results of the previous refinement and to prepare data for PDB deposition. In addition, the refinement results can be summarized graphically in the form of PostScript plots.

18.9.5. Distribution and support of *SHELX*

The *SHELX* system is available free to academics and, for a small licence fee, to commercial users. The programs are supplied as Fortran sources and as precompiled versions for widely used operating systems. The programs, examples and extensive documentation may be downloaded from the Internet or (if necessary) supplied on CD ROM. Details of new developments, answers to frequently asked questions, and information about obtaining and installing the programs are available from the SHELX home page, http://shelx.uni-ac.gwdg.de/SHELX/. The author is always interested to receive reports of problems and suggestions for improving the programs and their documentation by e-mail (gsheldr@shelx.uni-ac.gwdg.de).

Chapter 18.10. *PrimeX* and the Schrödinger computational chemistry suite of programs

J. A. Bell, Y. Cao, J. R. Gunn, T. Day, E. Gallicchio, Z. Zhou, R. Levy and R. Farid

18.10.1. Introduction

PrimeX is a new crystal structure refinement program for large biological molecules. Among the tools included in the package are reciprocal- and real-space minimization, automated construction of polypeptides into electron density, side-chain placement, ligand placement and simulated-annealing refinement. *PrimeX* is unique among X-ray refinement packages for large biological molecules with respect to its origins: the popular docking program, *Glide*, and the protein structure prediction and refinement package, *Prime*.

18.10.1.1. Computational environment

PrimeX is fully integrated with *Maestro*, a general-purpose molecular graphics front end. It shares a consistently designed interface with a suite of other powerful programs in molecular modelling and computational chemistry. Some of these other programs and their functions are listed in Table 18.10.1.1.

18.10.1.2. Mission

The first goal of *PrimeX* is to produce protein models consistent with both the X-ray diffraction data and the needs of computational chemists. Each of the software packages listed in Table 18.10.1.1 depends, to some degree, on accurate protein structures as input for computations. However, the models of biological molecules produced by crystallographers typically cause problems for computational work in two ways. First, these models lack coordinates for hydrogen atoms. Because the experimental data rarely give any direct indication of the correct position of hydrogen atoms, crystallographers are reluctant to include them in their models. Secondly, these models frequently contain coordinates that place non-bonded atoms implausibly close together, leading to the calculation of extremely high internal energy in these molecules. Crystallographers historically have not restrained these interactions as strongly as they restrain other elements of molecular geometry such as bond lengths, bond angles and group planarity. A reason for placing atoms in these conflicting positions is to fit the atoms at the centre of the observed electron-density peak, even if, because of atomic motion, that peak extends over a large volume of space that intersects with the volume occupied by other atoms. The result is a model that may be representative of the time-averaged structure but which cannot be consistent with the structure at a given instance. *PrimeX* produces a model that is consistent with both timescale views.

Table 18.10.1.1
Schrödinger software packages related to *PrimeX*

Package	Brief description
CombiGlide	Lead compound design and optimization
Desmond	High-performance molecular dynamics simulations
Glide	Ligand–receptor docking and scoring
Induced-Fit Docking	Modelling conformational changes induced by ligand binding
Liason	Ligand–receptor binding free-energy prediction
MacroModel	Full-featured program for molecular modelling
Prime	Protein structure prediction and refinement
QSite	Quantum mechanics/molecular mechanics calculations on biological systems
SiteMap	Binding-site identification and analysis

The second goal of *PrimeX* is to minimize unnecessary experimenter interaction for repetitive tasks. At its current stage of development, *PrimeX* provides a comprehensive set of features for automation of the refinement of the X-ray crystal structures of large biological molecules. Future development will combine these tools in automated multi-step processes.

18.10.1.3. Implementation path

In a field where most of the available software has been developed from academic sources, *PrimeX* is the only refinement program for biological crystallography that has been developed in a commercial environment. The advantage of commercial development includes high standards for consistency, professional software support and specific attention to the concerns of crystallographers in industry. All code is developed internally and intellectual property rights are monitored carefully. In an industrial setting, this assurance may be important to avoid future intellectual property entanglements.

18.10.2. Computational environment

Several aspects of the software packages listed in Table 18.10.1.1 are especially relevant to the application of *PrimeX*.

18.10.2.1. Molecular graphics

Maestro is the unified interface for all Schrödinger software. It has impressive rendering capabilities, a powerful selection of analysis tools and a set of fundamental tools for manipulating molecules. Hardware stereo is supported. Alternate conformations are displayed and can be manipulated in *Maestro*. Automation of complex tasks and development of custom applications can be accomplished through integrated Python scripting in *Maestro*, as well as through an internal macro facility. Function keys are also customizable. The results of each operation in a series of steps are organized in a project table (Fig. 18.10.2.1). This feature of *Maestro* is well suited to documenting the multiple steps typical of crystal structure refinement.

18.10.2.2. Supporting infrastructure

All Schrödinger programs are accessed through a clear, well organized graphical user interface (GUI). Nearly all computations are run through Schrödinger's job control facility. This facility provides a uniform mechanism for launching, monitoring and controlling calculations. Jobs can be submitted *from* any computer *to* any computer, cluster or grid, or to a batch queue, and the results returned to the computer from which the job was submitted. In addition, many of Schrödinger's tools have been integrated as *KNIME* extensions. *KNIME* (http://www.knime.org) is an open-source pipelining program which provides a graphical interface for building workflows. *PrimeX* components will also be available for *KNIME* workflows in the future.

18.10.2.3. *Molecular mechanics*

OPLS (Jorgensen *et al.*, 1996; Kaminski *et al.*, 2001) is a general-purpose force field for modelling proteins, nucleic acids and small molecules. This accurate description of atomic level interactions provides consistency across all Schrödinger molecular modelling packages, such as the core modelling functions of the *MacroModel* package or the molecular dynamics simulation tools of *Desmond*. *PrimeX* applies this consistent molecular description to the refinement of large biological crystal structures.

18.10.3. Achieving the mission of *PrimeX*

The main goal of any X-ray crystal structure refinement program is to produce an optimized fit to the X-ray diffraction data, consistent with known molecular stereochemistry. For *PrimeX*, the additional goal is to include hydrogen atoms in the model in a way that correctly reflects molecular stereochemistry, especially for non-bonded interactions.

18.10.3.1. *Molecular models and computational chemistry*

18.10.3.1.1. *Hydrogen atoms*

Although crystallographers have generally not included coordinates for hydrogen atoms in their models at moderate resolution, this situation has not always been so. During the early years of development of the very popular *XPLOR* package for refinement (Brünger, 1992), which was later augmented to become the even more popular refinement package *CNS* (Brünger *et al.*, 1998), the geometric restraints were based on the CHARMm force field. The presence of all polar hydrogen atoms, *i.e.* hydrogen atoms attached to non-carbon atoms, was required by this force field. Quite a number of structures from that era remain in the Protein Data Bank and include coordinates for polar hydrogen atoms. This CHARMm-based restraint system was later modified to a unified-atom model that is used by *CNS* today.

Use of the all-atom force field OPLS in *PrimeX* requires the explicit definition of all hydrogen-atom positions for geometric calculations. Hydrogen atoms are added to the model automatically in a manner that satisfies local hydrogen-bonding opportunities with adjacent atoms, if they are not already present from previous cycles of refinement. An additional hydrogen-bond optimization tool in *PrimeX* (Fig. 18.10.3.1) analyses donors and acceptors to define clusters of such sites that might be connected through hydrogen bonds, and that form networks. Within each cluster, hydrogen bonding is evaluated using a rule-based Monte Carlo method to find the optimal combinations of the variable components of these systems. The structural features adjusted during hydrogen-bond optimization are:

(i) alcoholic hydrogen-atom positions;
(ii) sulfhydril hydrogen-atom positions;
(iii) phenolic hydrogen-atom positions;
(iv) charge and tautomeric states of Asp and Glu side chains;
(v) charge, tautomeric states and orientation (flip) of His side chains;
(vi) orientation (flip) of Asn and Gln side chains; and
(vii) positions for hydrogen atoms in water molecules.

18.10.3.1.2. *Electrostatics and implicit solvation*

For hydrogen atoms bonded to more electronegative atoms, electrostatic forces are a major determinant of non-bonded interactions, and they must be evaluated during the calculation of geometric gradients in the refinement. Thus, *PrimeX* employs the complete molecular mechanics description of atomic interactions embodied in OPLS, including electrostatic terms. A solvation energy term (Zhu, Shirts & Friesner, 2007) can account for the effects of solvation on electrostatic interactions without the use of explicit coordinates for all solvent atoms. This term may be optionally included in the molecular-mechanics description used by *PrimeX*. Refinement incorporating a complete electrostatic description, including an implicit solvation term, has been shown to lead to lower $R_{\rm free}$ values compared with refinement excluding those interactions (Knight *et al.*, 2008). For cases where coordinates for bound water molecules were explicitly included in the refinement, the effects of an implicit solvation term on $R_{\rm free}$ were favourable but small (J. A. Bell, unpublished work). A more complete analysis of the effects of the implicit solvation term in *PrimeX* is in progress.

18.10.3.1.3. *van der Waals interactions*

The full OPLS force field includes terms for repulsive and attractive non-bonded interactions. Most significant for restraints during crystallographic refinement is the utilization of the full repulsive term for non-bonded interactions, unlike other leading biological crystal structure refinement packages where these terms are weighted relatively lightly.

The project table entries track the steps of this refinement in progress, using the model from PDB (Protein Data Bank; Berman *et al.*, 2000) entry 1mdq to solve the structure of entry 1mpd. The most important statistics for monitoring the course of the refinement are always easily available.

18.10.3.2. *Molecular models consistent with X-ray data*

All current programs for refinement of biological crystal structures employ geometric restraints that either originate with or are consistent with a survey of small-molecule structures by Engh & Huber (1991). Other geometric restraints for group planarity and non-bonded interactions have been added to each refinement package independently from different sources. *PrimeX* employs the internally consistent molecular description embodied in the OPLS force field to achieve

Figure 18.10.3.1

The hydrogen-bond network optimizer clusters hydrogen-bond donors and acceptors to group together those that could possibly interact, so that these interactions can be efficiently optimized. Individual clusters may be examined and optimized by the user as shown, or all of the clusters may be optimized in a single operation.

the same goal of restraining stereochemistry to values typical of small-molecule structures.

During refinement, all crystallographic calculations in *PrimeX* are made without any contribution from hydrogen atoms. This strategy avoids exacerbation of the problem of overfitting that would occur if hydrogen coordinates were also considered to be adjustable parameters in refinement. Rather, the hydrogen-atom coordinates in the model can be thought of as a means of applying the more accurate molecular description found in the OPLS force field, while the positions of non-hydrogen atoms are influenced by the crystallographic gradients. This distinct hybrid approach for the calculation of the two types of terms during refinement works well, despite the seeming asymmetry of the treatment (J. A. Bell, unpublished work).

18.10.3.3. Automation of refinement tasks

As well as executing through the graphical interface, most *PrimeX* tasks can be run through command-line execution, so these tasks can be easily integrated into workflows. Future development will be focused on combining multiple tasks and diagnostic information into larger automated tasks that will reduce the amount of routine work required from users during refinement.

18.10.4. *PrimeX* implementation and theory

18.10.4.1. Force-field model and automatic atom typing

An important feature of *PrimeX* is that all molecules are automatically treated with atom typing and parameters are generated without the intervention of the crystallographer. This capability saves a large amount of time that might otherwise be spent collecting this information from disparate sources. The use of OPLS in *PrimeX* thus ensures that all ligand and protein parameters are similarly scaled and are consistent between all parts of the structure.

18.10.4.2. Reciprocal-space calculations

18.10.4.2.1. Restrained maximum-likelihood minimization

For reciprocal-space refinement with a maximum-likelihood target, the formulation of Pannu & Read (1996) was implemented following the general concepts developed in the publications of Brünger and co-workers (Brünger, 1989; Brünger *et al.*, 1998). A maximum-likelihood target has been shown to improve the convergence of refinement and to reduce the effects of model bias (Murshudov *et al.*, 1997). Optionally, a more traditional least-squares target may be employed. Three different minimizers are provided: conjugate gradient, quasi-Newton and truncated Newton (Zhu, Shirts, Friesner & Jacobson, 2007). Parts of the model related by noncrystallographic symmetry may be restrained to be similar with respect to both coordinates and displacement parameters during refinement. All or parts of the structure can be easily grouped for rigid-body coordinate refinement. Refinement will automatically account for alternate conformations. Alternate conformations may vary in size and may encompass from just one atom to many residues. Restrained isotropic *B*-factor refinement is also provided. *B* factors may optionally be grouped by main-chain and side-chain atoms for each residue. Grouped occupancy refinement is also available.

18.10.4.2.2. Simulated annealing

Simulated-annealing refinement was implemented within the general-purpose molecular modelling package *IMPACT* (Banks *et al.*, 2005), employing concepts for simulated-annealing refinement validated in the program *CNS* (Adams *et al.*, 1997). *PrimeX* simulated annealing provides two alternative energy models for dynamic simulation refinement. In the complete method, all molecular-mechanics terms are evaluated during the simulation. In the approximate method, the electrostatic and implicit solvation terms are not evaluated, a method similar to that employed in *CNS* (Adams *et al.*, 1997).

18.10.4.2.3. Map generation

Map calculations in *PrimeX* are based on the sigma*A* weighting scheme of Read (1986), a data treatment that has been shown to decrease the bias in electron-density maps. Optionally, an unweighted map may be calculated.

18.10.4.2.4. Omit maps

Omit maps (Bhat & Cohen, 1984; Bhat, 1988) have been implemented because of their demonstrated ability to reduce model-derived bias in maps (Vellieux & Dijkstra, 1997). The kicked omit maps described by Guncar *et al.* (2000) have also been included in *PrimeX*. After all the atoms to be omitted have been removed from the coordinates for the calculation, the model is modified by adding a small displacement of random size and direction to each coordinate before the phases are calculated. This process is repeated multiple times and the multiple maps are averaged. Either of these methods can be applied in a composite manner where small portions of the structure are omitted systematically over the entire map volume. Finally, simulated-annealing omit maps can be calculated by deleting the atoms to be omitted from the model, followed by simulated-annealing refinement and automatic map generation.

Pick a density blob

Figure 18.10.4.1

The ligand/solvent placement GUI provides a list of electron-density blobs from a map with coefficients $F_o - F_c$, together with their volume, and several ways to specify the molecules to be placed into the electron density. Multiple molecules may be included in a single placement operation at a single site. Ligand-placement options include the generation of charge and tautomer states of the ligand with the program *LigPrep* and the inclusion of symmetry-related molecules in the calculation at the ligand site.

18.10.4.3. *Real-space tools*

18.10.4.3.1. *Loop refinement*

Polypeptide segments, both internal (loops) and external (tails), can be built from the target sequence as stored in the program. The program builds polypeptides according to an algorithm derived from the protein-modelling program *Prime* (Jacobson *et al.*, 2004; Zhu, Shirts & Friesner, 2007). Using the end of the existing structure as an anchor point, a residue is added and sampled in various conformations. All conformations that demonstrate even a modest fit to the electron density are kept. During the next addition, all stored conformations are used as starting points for sampling the conformation of the next residue. The total number of conformations may reach many thousands as additional residues are added. When all amino acids have been added, the conformations are clustered to reduce the redundancy of the set, treated with real-space minimization, scored by conformation (OPLS energy) and fitted to the electron density. When building loops, the structures are built from both ends of the structure gap. Only those pairs of built polypeptides that meet to form a contiguous loop are clustered, refined and evaluated. Typically, one to three of the highest scoring structures are returned by the program, depending on the quality of the electron density.

18.10.4.3.2. *Side-chain placement*

Also based on *Prime* technology, one or multiple side chains may be simultaneously evaluated and placed into electron density. Even if two side chains have overlapping conformations at the start of the process, they will both be placed into appropriate electron density. As an alternative, various common rotamers of side chains may be explored interactively in *Maestro* and the best fit to the electron density selected visually or automatically.

18.10.4.3.3. *Minimization*

Real-space minimization provides an additional method of optimizing model coordinates according to the electron density and force field, as well as playing an integral part in the building of polypeptide chains, the placement of amino-acid side chains and the placement of ligands.

18.10.4.4. *Water placement*

Waters may be added by *PrimeX* to difference electron-density maps for positive peaks exceeding a selected level of significance. Prospective water sites in the electron-density map are screened by three different criteria related to distance from other atoms. Water molecules that refine to a B factor above a selectable cutoff are deleted.

18.10.4.5. *Ligand placement*

Ligand placement can be accessed through a convenient GUI (Fig. 18.10.4.1). The algorithm for ligand placement was derived from the docking program *Glide* (Friesner *et al.*, 2004). In brief, the program abstracts the protein model as an energy grid in which the properties of the residues are encoded. Multiple conformations are generated for the ligand, and then a search is made for the best possible position and orientation in the vicinity of the electron density that the user has identified. The many alternative solutions are reduced in number with the application of a dual scoring system: (i) the GlideScore is an evaluation of the chemical complementarity between the ligand and the protein; (ii) the DensScore is a measure of the fit of the ligand to the observed electron density. Both of these scores are used to rank the fitting of each ligand conformation in each orientation. The weighting of the DensScore *versus* the GlideScore is under user control and it strongly favours the DensScore by default. Surviving candidates are subjected to rigid-body and torsion-angle refinement against an energy function that includes the OPLS energy and the DensScore. The weighting of the DensScore *versus* the OPLS energy is also under user control, and it strongly favours the DensScore by default. Finally, the top few dozen candidates are treated with real-space refinement and are ranked by real-space R factor. The top five poses for the ligand are returned with the protein structure for evaluation by the user.

18.10.4.6. *Validation*

PrimeX provides three main validation tools. 'Protein reports' lists geometric variations from expected values in table form. This table can be sorted by residue or by the magnitude of the deviation, to highlight parts of the structure most in need of attention. A density fit table (Fig. 18.10.4.2) lists the real-space R factors for each main chain and side chain and for the entire residue. This table can also be sorted by any column. Clicking on any row of either table centres the molecular display on that

The density fit table provides a convenient method for finding residues where the main chain or side chain in the model poorly fits the electron density. Clicking on the line for Lys118 in chain A centres that residue in the workspace display, allowing the user to bring to bear the appropriate tool to resolve the problem.

residue. An interactive Ramachandan plot provides additional analysis of main-chain structure.

18.10.5. Conclusion

PrimeX is a combination of well established methodology with innovations focused on producing the most useful model from the refinement of biological molecules. Future directions to be explored will include TLS scaling (Winn *et al.*, 2003), increasing levels of automation, more reliable water placement, and refinement of ensembles of structures as a means of representing the flexibility of the molecule and the uncertainty of the atomic positions (Knight *et al.*, 2008).

Chapter 18.11. *PHENIX*: a comprehensive Python-based system for macromolecular structure solution

P. D. Adams, P. V. Afonine, G. Bunkóczi, V. B. Chen, I. W. Davis, N. Echols, J. J. Headd, L.-W. Hung, G. J. Kapral, R. W. Grosse-Kunstleve, A. J. McCoy, N. W. Moriarty, R. Oeffner, R. J. Read, D. C. Richardson, J. S. Richardson, T. C. Terwilliger and P. H. Zwart

18.11.1. Foundations

18.11.1.1. PHENIX architecture

The *PHENIX* (Adams *et al.*, 2002) architecture is designed from the ground up as a hybrid system of tightly integrated interpreted ('scripted') and compiled software modules. A mix of scripted and compiled components is invariably found in all major successful crystallographic packages, but often the scripting is added as an afterthought in an *ad hoc* fashion using tools that predate the object-oriented programming era. While such *ad hoc* systems are quickly established, they tend to become a severe maintenance burden as they grow. In addition, users are often forced into many time-consuming routine tasks such as manually converting file formats. In *PHENIX*, the scripting layer is the heart of the system. With only a few exceptions, all major functionality is implemented as modules that are exclusively accessed *via* the scripting interfaces. The object-oriented Python scripting language (Lutz & Ascher, 1999) is used for this purpose. In about two decades, a large developer/user community has produced millions of lines of highly uniform, interoperable, mature and openly available sources covering all aspects of programming ranging from simple file handling to highly sophisticated network communication and fully featured cross-platform graphical interfaces. Embedding crystallographic methods into this environment enables an unprecedented degree of automation, stability and portability. By design, the object-oriented programming model fosters shared collaborative development by multiple groups. It is routine practice to hierarchically recombine modules written by different groups into ever more complex procedures that appear uniform from the outside. A more detailed overview of the key software technology leading to all these advances, presented in the context of crystallography, can be found in Grosse-Kunstleve *et al.* (2002).

In addition to the advantages outlined in the previous paragraph, the scripting language is generally most efficient for the rapid development of new algorithms. However, runtime performance considerations often dictate that numerically intensive calculations are eventually implemented in a compiled language. The first choice of a compiled language is of course to reuse the same language environment as used for the scripting language itself, which is a C/C++ environment. Not only is this the mainstream software environment on all major platforms used today, but with probably hundreds of millions of lines of C/C++ sources in existence it is an environment that is virtually guaranteed to thrive in the long term. An in-depth discussion of the combined use of Python and C++ can be found in Grosse-Kunstleve *et al.* (2002) and Abrahams & Grosse-Kunstleve (2003). This model is used throughout the *PHENIX* system.

18.11.1.2. Graphical user interface

A new graphical user interface (GUI) for *PHENIX* was introduced in version 1.4. It uses the open-source wxPython toolkit, which provides a 'native' look on each operating system. Development has focused on providing interfaces around the existing command-line programs with minimal modification, using the same underlying configuration system (*libtbx.phil*; Grosse-Kunstleve *et al.*, 2005) as used by most *PHENIX* programs as a template to automatically generate controls. Because these programs are implemented primarily as Python modules, complex data including models, reflections and other viewable data may be exchanged with the GUI without resorting to parsing log files. The current *PHENIX* release (version 1.5) includes GUIs for *phenix.refine* (Afonine *et al.*, 2005), *phenix.xtriage* (Zwart *et al.*, 2005), the *AutoSol* (Terwilliger *et al.*, 2009), *AutoBuild* (Terwilliger, Grosse-Kunstleve, Afonine, Moriarty, Adams *et al.*, 2008) and *LigandFit* (Terwilliger *et al.*, 2006) wizards, the restraints editor *REEL*, all of the validation tools and several utilities for creating and manipulating maps and reflection files. More recent builds of *PHENIX* contain a new GUI for the *AutoMR* wizard and future releases will include a new interface for *Phaser* (McCoy *et al.*, 2007).

Intrinsically graphical data is visualized with embedded graphs (using the free matplotlib Python library) or a simple OpenGL viewer. This simplifies the most complex parameters, such as atom selections in *phenix.refine*, which can be visualized or picked interactively with the built-in viewer. The GUI also serves as a platform for additional automation and user customization. Similarly to the *CCP*4 interface (*CCP*4*i*; Potterton *et al.*, 2003), *PHENIX* manages data and task history for separate user-defined projects. Default parameters and input files can be specified for each project; for instance, the generation of ligand restraints from the *phenix.refine* GUI gives the user the option of automatically loading these restraints in future runs.

The popularity of Python as a scientific programming language has led to its use in many other structural-biology applications, especially molecular-graphics software. The *PHENIX* GUI includes extension modules for the modeling programs *Coot* (Emsley & Cowtan, 2004; Chapter 17.1) and *PyMOL* (DeLano, 2002), both of which are controlled remotely from *PHENIX* using the XML-RPC protocol. This allows the interfaces to integrate seamlessly; any model or map in *PHENIX* can be automatically opened in *Coot* with a single click. In programs that iteratively rebuild or refine structures, such as *AutoBuild* and *phenix.refine*, the current model and maps will be continually updated in *Coot* and/or *PyMOL* as soon as they are available. In the validation utilities, clicking on any atom or residue flagged for poor statistics will recentre the graphics windows on that atom. Remote control of the *PHENIX* GUI is also simple, using the same protocol, and simple extensions to the *Coot* interface provide direct launching of *phenix.refine* with a model preloaded.

18.11.2. Analysis of experimental data

PHENIX has a range of tools for the analysis, validation and manipulation of X-ray diffraction data. A comprehensive tool for analysing X-ray diffraction data is *phenix.xtriage* (Zwart *et al.*, 2005), which carries out tests ranging from space-group determination and detection of twinning to detection of anomalous signal. These tests provide the user and the various wizards with a set of statistics that characterize a data set. For analysis of twinning, *phenix.xtriage* consolidates a number of statistics to provide a balanced verdict of possible symmetry and twin-related issues with the data. *Phenix.xtriage* provides the user with feedback on the overall characteristics of the data. Routine usage of *phenix.xtriage* during or immediately after data collection has resulted in the timely discovery of twinning or other issues (Flynn *et al.*, 2007; Kostelecky *et al.*, 2009). Detection of these idiosyncrasies in the data typically reduces the overall effort in a successful structure determination.

A likelihood-based estimation of the overall anisotropic scale factor is performed using the likelihood formalism described by Popov & Bourenkov (2003). Database-derived standard Wilson plots for proteins and nucleic acids are used to detect anomalies in the mean intensity. These anomalies may arise from ice rings or other issues (Morris *et al.*, 2004). Data strength and low-resolution completeness are also analysed. The presence of anomalous signal is detected by analysis of the measurability, a quantity expressing the fraction of statistically significant Bijvoet differences in a data set (Zwart, 2005). The native Patterson function is used to detect the presence of pseudo-translational symmetry. A database-derived empirical distribution of maximum peak heights is used to assign significance to detected peaks in the Patterson function.

A comprehensive automated twinning analysis is performed. Twin laws are derived from first principles to facilitate the identification of pseudo-merohedral cases. Amplitude and intensity ratios, $\langle |E^2 - 1| \rangle$ values, the L statistic (Padilla & Yeates, 2003) and $N(Z)$ plots are derived from data cut to the resolution limit suggested by the data-strength analysis. The removal of shells of data with relatively high noise content greatly improves the automated interpretation of these statistics. A Britton plot, H test and a likelihood-derived approach are used to estimate twin fractions when twin laws are present. If a model has been supplied, an R *versus* R (Lebedev *et al.*, 2006) analysis is carried out. This type of analysis is of particular use when dealing with pseudo-symmetry, space-group problems and twinning (Zwart *et al.*, 2008).

To test for inconsistent indexing between different data sets, a set of reindexing laws is derived from first principles given the unit cells and space groups of the sample and reference data sets. A correlation analysis suggests the most likely choice of re-indexing of the data. Analysis of the metric symmetry of the unit cell provides a number of likely point groups. A likelihood-inspired method is used to suggest the most likely point group of the data. Subsequent analysis of systematic absences in a likelihood framework ranks subsequent space-group possibilities (details to be published).

18.11.3. Substructure determination, phasing and molecular replacement

After ensuring that the diffraction data are sound and understood, the next critical necessity for solving a structure is the determination of phases using one of several strategies (Adams, Afonine *et al.*, 2009).

18.11.3.1. Substructure determination

The substructure-determination procedure implemented as *phenix.hyss* (*Hybrid Substructure Search*; Grosse-Kunstleve & Adams, 2003) combines the multi-trial dual-space recycling approaches pioneered by *Shake-and-Bake* (Miller *et al.*, 1994) and later *SHELXD* (Sheldrick, 2008) with the use of the fast translation function (Navaza & Vernoslova, 1995; Grosse-Kunstleve & Brunger, 1999). The fast translation function is the basis for a systematic search in the Patterson function (performed in reciprocal space), in contrast to the stochastic alternative of *SHELXD* (performed in direct space). *Phenix.hyss* is the only substructure-determination program to fully integrate automatic comparison of the substructures found in multiple trials *via* a Euclidean model matching procedure (part of the *cctbx* open-source libraries). This allows *phenix.hyss* to detect whether the same solution was found multiple times and to terminate automatically if this is the case. Extensive tests with a variety of single-wavelength anomalous diffraction (SAD) data sets (Grosse-Kunstleve & Adams, 2003) have led to a parameterization of the procedure that balances runtime considerations and the likelihood that repeated solutions present the correct substructure. In many cases the procedure finishes in seconds if the substructure is detectable from the input data.

18.11.3.2. Phasing

Phaser, available in *PHENIX* as *phenix.phaser*, applies the principle of maximum likelihood to solving crystal structures by molecular replacement, by SAD or by a combination of both. The likelihood targets take proper account of the effects of different sources of error (and, in the case of SAD phasing, their correlations) and allow different sources of information to be combined. In solving a molecular-replacement problem with a number of different components, the information gained from a partial solution increases the signal in the search for subsequent components. Because the likelihood scores for different models can be directly compared, decisions among models can readily be made as part of automation strategies (discussed below).

18.11.3.3. Noncrystallographic symmetry (NCS)

Noncrystallographic symmetry is an important feature of many macromolecular crystals that can be used to greatly improve electron-density maps. *PHENIX* has tools for the identification of NCS and for using NCS and multiple crystal forms of a macromolecule in phase improvement.

Phenix.find_ncs and *phenix.simple_ncs_from_pdb* are tools for the identification of noncrystallographic symmetry in a structure using information from a heavy-atom substructure or an atomic model. *Phenix.simple_ncs_from_pdb* will identify NCS and generate transformations from the chains in a model in a PDB file. *Phenix.find_ncs* will identify NCS from either a heavy-atom substructure (Terwilliger, 2002*a*) or the chains in a PDB file and will then compare this NCS with the density in a map to verify that the NCS is actually present.

Phenix.multi_crystal_average is a method for combining information from several crystal forms of a structure. It is especially well suited to cases where each crystal form has its own NCS, adjusting phases for each crystal form so that all the NCS copies in all crystals are as similar as possible.

NCS restraints should normally be applied in density modification and model building in all cases except where there is clear evidence that NCS is not present. In density modification within *PHENIX* the presence of NCS is identified from the heavy-atom sites or from an atomic model if available. The local correlation of density in NCS-related locations is then used automatically to set variable restraints on NCS symmetry in the map. In refinement, NCS symmetry is applied through coordinate restraints, targeting the positions of each NCS copy relative to those of the other NCS-related chains. The default NCS restraints in *PHENIX* are very tight, with targets of 0.05 Å r.m.s. At resolutions lower than about 2.5 Å these tight restraints on NCS should usually be applied. At higher resolutions it may be appropriate to use looser restraints or to remove them altogether. Additionally, if there are segments of the chains that clearly do not obey the NCS relationships they should be excluded from the NCS restraints. Normally this is performed automatically, but it can also be specified explicitly.

18.11.4. Model building, ligand fitting and nucleic acids

Key steps in the analysis of a macromolecular crystal structure are building an initial core model, identification and fitting of ligands into the electron-density map and building an atomic model for loop regions that are less well defined than the majority of the structure. *PHENIX* has tools for rapid model building of secondary structure and main-chain tracing (*phenix.find_helices_strands*) and for the fitting of flexible ligands (*phenix.ligandfit*) as well as for fitting a set of ligands to a map (*phenix.find_all_ligands*) and for the identification of ligands in a map (*phenix.ligand_identification*). *PHENIX* additionally has a tool for the fitting of missing loops (*phenix.fit_loops*). Validation tools are provided so that the models produced can be validated at each step along the way.

18.11.4.1. Model building

Phenix.find_helices_strands will rapidly build a secondary-structure-only model into a map or very rapidly trace the polypeptide backbone of a model into a map. To build secondary structure in a map, *phenix.find_helices_strands* identifies α-helical regions and β-strand segments, models idealized helices and strands into the corresponding density, allowing for bending of the helices and strands, and assembles these into a composite model. To very rapidly trace the main chain in a map, *phenix.find_helices_strands* finds points along ridgelines of high density where Cα atoms might be located, identifies pairs and then triplets of these Cα atoms that have density between the atoms and plausible geometry, constructs all possible connections of these Cα atoms into nonamers and then identifies all the longest possible chains that can be made by joining the nonamers. This process can build a Cα model at a rate of about 20 residues per second, yielding a backbone model that can readily be interpreted visually or automatically to evaluate the quality of the map that it is based on.

Phenix.fit_loops will fit missing loops in an atomic model. It uses *RESOLVE* model building (Terwilliger, 2003*a*,*b*,*c*) to extend the chain from either end where a loop is missing and to connect the chains into a loop with the expected number of residues.

18.11.4.2. Ligand fitting

Phenix.ligandfit is a tool for fitting a flexible ligand into an electron-density map (Terwilliger *et al.*, 2006). The key approaches used are breaking the ligand into its component rigid-body parts, finding where each of these can be placed into density, tracing the remainder of the ligand based on the positions of these core rigid-body parts and re-combining the best parts of multiple fits while scoring based on the fit to the density.

Phenix.find_all_ligands is a tool for finding all the instances of each of several ligands in an electron-density map. *Phenix.find_all_ligands* finds the largest contiguous region of unused density in a map and uses *phenix.ligandfit* to fit each supplied ligand into that density. It then chooses the ligand that has the highest real-space correlation to the density (Terwilliger, Adams *et al.*, 2007). It then repeats this process until no ligands can be satisfactorily fitted into any remaining density in the map.

Phenix.ligand_identification is a tool for identifying which ligands are compatible with unknown electron density in a map (Terwilliger, Adams *et al.*, 2007). It can search using the 200 most common ligands from the PDB or from a user-supplied list of ligands. *Phenix.ligand_identification* uses *phenix.ligandfit* to fit each ligand to the map and identifies the best-fitting ligand using the real-space correlation and surface complementarity of the ligand and the atoms in the structure surrounding the ligand-binding site.

18.11.4.3. RNA and DNA

In common with most macromolecular crystallographic tools, *PHENIX* was originally developed with protein structures primarily in mind. Now that nucleic acids, and especially RNA, are increasingly important in large biological structures, the system is being modified in places where subtle differences in procedure are needed rather than just the relevant libraries.

Model building in *phenix.autobuild* now has a preliminary set of nucleic acid procedures that take advantage of the relatively well determined phosphate and base positions, as well as the preponderance of double helix, and in the future will make use of the RNA backbone conformers recently defined by the RNA Ontology Consortium (Richardson *et al.*, 2008). Nucleic acid structures benefit significantly from torsion-angle refinement, which has recently been added to the options in *phenix.refine*. A principal problem in RNA models is getting the ribose pucker correct, although it is known to consist almost entirely of either C3′-*endo* (which is commoner and that found in the A-form helix) or C2′-*endo* (Altona & Sundaralingam, 1972). *MolProbity* uses the perpendicular distance from the 3′ phosphate to the line of the C1′—N1/9 glycosidic bond as a reliable diagnostic of ribose pucker (Davis *et al.*, 2007; Chapter 21.6). This same test has now been built into *phenix.refine* to allow the use of pucker-specific target parameters for bond lengths, angles and torsions (Gelbin *et al.*, 1996) rather than the uneasy compromise values (Parkinson *et al.*, 1996) used in most pucker-agnostic refinement. Currently, if an incorrect pucker is diagnosed it must usually be fixed by user rebuilding, for instance in *Coot* (Emsley & Cowtan, 2004; Chapter 17.1) or in *RNABC* (Wang *et al.*, 2008). A rebuilding functionality will probably be incorporated into *PHENIX* soon, but in the meantime the refinement will now correctly maintain the geometry of a C2′-*endo* pucker once it has been built and identified using conformation-specific residue names.

18.11.4.4. Maps, models and avoiding bias

Phenix.refine (and the graphical tool *phenix.maps*) can produce various types of maps, including anomalous difference, maximum-likelihood weighted ($p{*}mF_{\rm obs} - q{*}DF_{\rm model})\exp(i\alpha_{\rm model})$ and regular $(p{*}F_{\rm obs} - q{*}F_{\rm model}) \times \exp(i\alpha_{\rm model})$, where p and q are any user-defined numbers, filled and kick maps. The coefficients m and D of likelihood-weighted maps (Read, 1986) are computed using test-set reflections as described in Lunin & Skovoroda (1995) and Urzhumtsev *et al.* (1996).

Data incompleteness, especially systematic incompleteness, can cause map distortions (Lunin, 1988; Tronrud, 1997). An approach to remedying this problem is to replace ('fill') missing observations with nonzero values. One can use $DF_{\rm model}$ (similarly to *REFMAC*; Murshudov *et al.*, 1997) to replace the missing $F_{\rm obs}$ or use $\langle F_{\rm obs}\rangle$, where the $F_{\rm obs}$ are averaged across a resolution bin around the missing $F_{\rm obs}$ value. Based on a limited number of tests, both 'filling' schemes produce similar results, reiterating the importance of phases. However, it is important to keep in mind that by replacing missing $F_{\rm obs}$ there is a risk of introducing bias and, obviously, the more incomplete the data are the larger the risk. At present it is advisable to use both maps simultaneously: filled and not filled.

An average kick map (AK map; Gunčar *et al.*, 2000; Turk, 2007; Pražnikar *et al.*, 2009) is the result of the following procedure. A large ensemble of structures is created where the coordinates of each structure from the ensemble are all randomly shaken. A map is then computed for each structure. Finally, all maps are averaged to generate one AK map. An AK map is expected to have less bias and less noise and to enhance the existing signal, and can potentially clarify some initially bad densities.

A computationally intensive but powerful method of creating a very low bias map is to carry out iterative model building and refinement while omitting one region of the map from all calculations of structure factors (Terwilliger, Grosse-Kunstleve, Afonine, Moriarty, Adams *et al.*, 2008). The *phenix.autobuild* iterative-build OMIT map procedure carries this out automatically for either a single OMIT region or for overlapping OMIT regions to create a composite iterative-build OMIT map.

18.11.5. Model, and model-to-data, validation

The result of crystallographic structure determination is the atomic model. There are three principal components in assessing model quality: the covalent model geometry, the model stereochemistry and the quality of fit between the model and experimental data in both real space and in reciprocal space. All three provide overall measures, and the first two plus the real-space aspect of the third also provide checks for local outliers, which give the best leverage for user intervention to actively improve model accuracy (Arendall *et al.*, 2005). (Validation of the experimental data was described in Section 18.11.2 above.) *PHENIX* includes many individual tools for specific aspects of validation, plus several systems that combine those results into overall summaries. Validation is provided both for user evaluation of the progress and results of a structure solution and also to help inform the automated choices made by other parts of the system.

Most aspects of the *MolProbity* model-validation tools (Davis *et al.*, 2007; Chapter 21.6) have been adapted or rewritten for integrated use within *PHENIX* and are presented to the user by the new GUI (Section 18.11.1.2). H atoms are added by *phenix.reduce*, with optimization of entire local hydrogen-bond networks, consideration of the first layer of crystallographic waters and optional correction of side-chain amide or histidine 180° 'flips' (Word, Lovell, Richardson & Richardson, 1999). All-atom contacts (Word, Lovell, LaBean *et al.*, 1999) are calculated by *phenix.probe*, which provides the atomic overlap information needed for the validation of serious all-atom steric clashes, and can also be visualized in *Coot*. For the *PHENIX* GUI, the set of *MolProbity*-based tools provides both overall model statistics, such as clashscore and percentage of outliers, and detailed lists of the Ramachandran (Lovell *et al.*, 2003), rotamer (Lovell *et al.*, 2000), Cβ deviation (Lovell *et al.*, 2003) and clash outliers. The GUI also provides access to comprehensive validation kinemage graphics visualized in three dimensions in the graphical package *KiNG* (Chen *et al.*, 2009; Chapter 21.5), now included in *PHENIX*. Command-line tools are available for these validation methods: *phenix.rotalyze*, *phenix.ramalyze*, *phenix.cbetadev*, *phenix.clashscore*, *phenix.rna_validate*, *phenix.kinemage* (multi-criterion kinemage generation), *phenix.king*, *phenix.reduce* and *phenix.probe*. Additionally, *phenix.validate_model*, which analyses the deviations of bond lengths, bond angles, planarity *etc.* from ideal library values, complements the *MolProbity* torsional and atomic clash tools.

Phenix.real_space_correlation asserts the local model-to-data correspondence by providing a quantitative measure of how the atomic model fits the electron-density map at the residue or atom level (depending on the resolution). Rapidly obtaining a snapshot of global figures of merit for a crystallographic model and associated experimental data is a frequent task that is performed at all stages of structure solution. This task can be complicated for several reasons: the presence of novel ligands or nonstandard residues in the PDB-format (Berman *et al.*, 2000) coordinate file, data collected from twinned crystals, various reflection data file formats, different representation of atomic displacement parameters in the presence of TLS (Schomaker & Trueblood, 1968), experimental data type (X-ray and/or neutron), and files with multiple models and various formatting issues. *Phenix.model_vs_data* (Afonine, Grosse-Kunstleve *et al.*, 2010) is designed to automatically handle all these complications with minimal user input (a PDB file and a reflection data file) and provide a concise summary output. *Phenix.polygon* (Urzhumtseva *et al.*, 2009) is a graphical tool that is designed to indicate the similarity of validation parameters, such as free R value, for a particular structure compared with those deposited in the PDB. This comparison is performed for all other structures solved at similar resolution limits. The result is presented graphically. *Phenix.validation* combines all of the tools described above in one GUI, providing a single place for assessing the results of structure determination.

18.11.5.1. Model and structure-factor manipulation and analysis

PHENIX has a range of tools for displaying, analysing and manipulating structure-factor and model information. *Phenix.mtz.dump* and *phenix.cif_as_mtz* display and convert structure-factor data. *Phenix.print_sequence*, *phenix.pdb_atom_selection* and *phenix.pdbtools* display and manipulate coordinate files.

Phenix.tls is a tool for the extraction and manipulation of TLS information. Using this tool, TLS matrices and selections can be extracted from *REFMAC*- or *PHENIX*-formatted PDB file headers and the total or residual atomic B factors can be computed and output. Future functionality will include the complete analysis of TLS matrices and their graphical visualization.

Phenix.get_cc_mtz_mtz and *phenix.get_cc_mtz_pdb* are tools for analysing the agreement between maps based on a pair of MTZ files or between maps calculated from an MTZ file and a PDB file. The key attributes of these tools are that they automatically search all allowed origin shifts that might relate the two maps and that they write out a modified version of one of the MTZ files or of the PDB file, shifted to match the other.

18.11.6. Structure refinement

Phenix.refine is the state-of-the-art crystallographic structure-refinement engine of *PHENIX*. The foundational refinement machinery is a combination of highly efficient programming tools and new or rethought crystallographic algorithms. *Phenix.refine* possesses an extensive set of tools that cover the majority of refinement scenarios at any data resolution from low to ultra-high. Various reflection-data formats (for example, *CNS*, MTZ and *SHELX*) are recognized automatically. The input experimental data are checked for outliers (Read, 1999; Zwart *et al.*, 2005) and any reflections identified as such are excluded from the refinement calculations. Twinning can also be taken into account by providing a twin-law operator, which can be obtained using *phenix.xtriage*. Both X-ray and/or neutron diffraction data can be used and an option for joint XN refinement is available (simultaneous refinement against X-ray and neutron data; Adams, Mustyakimov *et al.*, 2009). Each refinement run begins with robust mask-based bulk-solvent correction and anisotropic scaling (Afonine *et al.*, 2005). Tools such as efficient rigid-body refinement (multiple-zones algorithm; Afonine *et al.*, 2009), simulated-annealing refinement (Brünger *et al.*, 1987) in Cartesian or torsion-angle space (Grosse-Kunstleve *et al.*, 2009), and automatic NCS detection and its use as restraints in refinement are important at low resolution and in the initial stages of refinement. A broad range of atomic displacement parameterizations are available, including grouped isotropic, constrained anisotropic (TLS) and individual atomic isotropic or anisotropic, allowing efficient modelling of atomic displacement parameters at any resolution (Afonine, Urzhumtsev *et al.*, 2010). Occupancy refinement (grouped, individual, group constrained for alternative conformations or any mixture) can be performed for any user-defined atoms. Atoms in alternative conformations are recognized automatically based on altLoc identifiers in the input PDB file and their occupancies are refined by default. Ordered solvent (water) model updating is integrated into the refinement process.

The availability of ultra-high-resolution data makes it possible to visualize the residual density arising from bonding effects; *phenix.refine* employs a novel interatomic scatterers model (Afonine *et al.*, 2007) to adequately account for these features. A flexible parameterization of H atoms allows their use at any resolution from subatomic (where their parameters can be refined individually) to low resolution (where a riding model is used). Refinement can be performed using a variety of refinement target functions, including maximum likelihood, maximum likelihood with experimental phase information and amplitude least squares. The refinement of coordinates can be performed in real or reciprocal space (allowing dual-space refinement). Novel ligands can easily be included in refinement by providing a corresponding CIF file as input (the CIF file can be automatically created using *phenix.ready_set*).

Manual fixing of amino-acid side-chain rotamers can be time-consuming, especially for large structures. Although the use of simulated-annealing refinement increases the convergence radius, it can still fail to fit incorrectly modelled side chains into the correct density. *Phenix.refine* has an option for automatic selection of the best rotamer based on a rotamer library (Lovell *et al.*, 2000) and optimal fit into the density (details to be published elsewhere). Furthermore, coupling real-space refinement with the built-in rotamer library and available *MolProbity* tools allows the automated identification and robust correction of common systematic errors involving backward-fit conformations for Leu, Thr, Val, Ile and Arg side chains, as developed and tested in the *Autofix* method (Headd *et al.*, 2009).

Phenix.refine allows multi-step complex refinement protocols in which most of the available refinement strategies can be combined with each other and applied to any selected part of the model. For example, a run of *phenix.refine* may perform rigid-body refinement, simulated annealing, individual and grouped B factors combined with TLS refinement, constrained occupancy refinement and automatic water picking.

The output of *phenix.refine* includes various maps (maximum-likelihood weighted, kicked, incompleteness corrected, anomalous difference and those with any user-defined coefficients), complete model and data statistics and a PDB file with a formatted REMARK 3 header ready for PDB deposition. The *phenix.refine* GUI is integrated with *Coot* and *PyMOL*, allowing seamless visual analysis of the refined model and associated maps.

Phenix.refine is tightly integrated with other *PHENIX* components, making structure solution, building and refinement a one-step process (for example, in the *AutoMR* and *AutoBuild* wizards). It is routinely tested by automatic re-refinement of all models in the PDB for which the experimental data are available.

18.11.6.1. Ligand-coordinate and restraint-geometry generation

The *electronic Ligand Builder and Optimization Builder* (*eLBOW*; Moriarty *et al.*, 2009) is a suite of tools designed for the reliable generation of Cartesian coordinates and geometry restraints for both novel and known ligands. In line with the rest of the *PHENIX* package, the *eLBOW* modules are written in Python, with the numerically intensive portions of the code written in C++. *eLBOW* is a flexible platform for converting a majority of common chemical inputs to optimized three-dimensional coordinates and geometry restraints for refinement. Ligand geometries can be minimized using the semi-empirical AM1 quantum-chemical method (Stewart, 2004), a numerically efficient and chemically accurate technique for the class of molecules commonly complexed with or bound to proteins.

In addition, a graphical user interface for editing geometry restraints and simple geometry manipulation of ligands has been developed. The *Restraints Editor, Especially Ligands* (*REEL*) removes the tedium of manually editing a restraints file by providing a number of commonly performed actions *via* pull-down menus and other interactive features. The effect of changes in the restraints can be immediately reflected in the molecule view to provide user feedback.

A tool that uses many of the features of *eLBOW* to quickly and more easily prepare a protein model for refinement is known as *ReadySet!* The flexibility of the Python interface is exemplified by the use of *Reduce*, *eLBOW* and several smaller portions of the *cctbx* toolkit to add H and/or D atoms to the model, ligands and water and to generate metal-coordination files and geometry restraints for unknown ligands. The files required for covalently bound ligands are also generated.

18.11.7. Integrated structure determination

18.11.7.1. Why automation?

Automation has dramatically changed macromolecular crystallography over the past decade, both by greatly speeding up the process of structure solution, model building and refinement and by bringing the tools for structure determination to a much wider group of scientists. As automation becomes increasingly comprehensive, it will allow users to test many more possibilities for structure determination, will allow improved estimation of uncertainties in the final structures and will allow the determination of ever more complex and difficult structures.

The *PHENIX* environment has been developed with automation as a key and defining feature. Each tool within *PHENIX* can seamlessly and nearly effortlessly be incorporated as part of any other tool or process in *PHENIX*. This means that very complex tasks can be built up from well tested and characterized tools and that tools and higher-level methods can be re-used in many different contexts. With a full automatic regression testing system as an integral part of the *PHENIX* environment, all these tasks and high-level methods are tested daily to ensure the integrity of the entire *PHENIX* system.

18.11.7.2. Automated structure solution

PHENIX has fully integrated structure-solution capability for both experimental phasing [multiwavelength anomalous diffraction (MAD), SAD, multiple isomorphous replacement (MIR) and combinations of these], carried out by *phenix.autosol*, and for molecular replacement, performed by *phenix.automr*. Each of these automated procedures feeds directly into the iterative model building, density modification and refinement of *phenix.autobuild*.

Phenix.autosol is designed to allow complete automation of experimental phasing while allowing a high degree of flexibility for advanced users. Beginning with structure-factor amplitudes and the sequence of the macromolecule, *phenix.autosol* uses *phenix.solve* (Terwilliger & Berendzen, 1999) to scale all data sets, *phenix.xtriage* (Zwart *et al.*, 2005) to analyse the data for twinning and to correct any anisotropy in the data and *phenix.hyss* (Grosse-Kunstleve & Adams, 2003) to find potential heavy-atom or anomalously scattering atoms. *Phenix.autosol* carries out experimental phasing with *phenix.phaser* (McCoy *et al.*, 2004, 2007) or *phenix.solve* (Terwilliger & Berendzen, 1999), density modification with *phenix.resolve* (Terwilliger, 1999) and preliminary model building using the methods in *phenix.autobuild* (Terwilliger, Grosse-Kunstleve, Afonine, Moriarty, Zwart *et al.*, 2008).

A key step in automated structure solution is the identification of which of several possible space-group and heavy-atom or anomalously scattering-atom substructures is correct. *Phenix.autosol* uses a Bayesian scoring algorithm based on analysis of the experimental electron-density maps to identify which substructures lead to the best maps (Terwilliger *et al.*, 2009). The main features of the maps that are used in this evaluation are the skewness of the electron density (non-Gaussian histogram of density with more density in the positive tail than the negative tail) and the correlation of local r.m.s. density (large contiguous regions of high variation where the molecule is located and separate large contiguous regions of low variation where the solvent is located).

Phenix.autosol is highly flexible, allowing any combination of experimental data, such as MAD + SIRAS (single isomorphous replacement with anomalous scattering) or several SAD data sets. Although it is fully automated, the user can control nearly all aspects of the operation of the procedure, including the scoring criteria and decisions about how certain *phenix.autosol* should be that the correct solution is contained in the current lists of solutions.

Phenix.autosol can carry out phasing using a combination of experimental SAD data and molecular-replacement information. If a molecular-replacement model is available, *phenix.autosol* will use *phenix.phaser* (McCoy *et al.*, 2004, 2007) to complete the anomalous substructure iteratively by constructing log-likelihood gradient maps for the anomalous scatterers based on the model of the non-anomalous structure and any anomalous scatterers that have already been found. The anomalous substructure is then used along with the model to calculate phases with *phenix.phaser*.

Phenix.automr carries out automated likelihood-based molecular replacement using *phenix.phaser* (Read, 2001; McCoy *et al.*, 2005, 2007; McCoy, 2007). The procedure is highly automated, allowing several copies of each of several components to be placed in a single run, which can also test different possible choices of space group. If there are alternative choices of model for a component, the molecular-replacement calculation can try each of them in turn or combine them as a statistically weighted ensemble. Although the evaluation of the likelihood targets is slow (Read, 2001), the use of fast approximations for the rotation search (Storoni *et al.*, 2004) and the translation search (McCoy *et al.*, 2005) gives run times that are competitive with traditional Patterson-based methods. Likelihood has been demonstrated to be more sensitive to the correct solution, particularly in difficult cases (Read, 2001). When there are several copies or several components to place, the ability of the likelihood functions to take advantage of preliminary partial solutions can provide a crucial increase in the signal.

18.11.7.3. Iterative model building, density modification and refinement

Phenix.autobuild is a highly integrated and automated procedure for model building and model improvement through iterative model building, density modification and refinement. *Phenix.autobuild* uses *phenix.resolve* (Terwilliger, 2003*a*,*b*) to carry out model building, model extension, model assembly, loop fitting and building outside existing models. It further uses *phenix.resolve* to improve electron-density maps with statistical density modification, including information from the newly built models as well as that obtained from experiment (*e.g. phenix.autosol*), from NCS (Terwilliger, 2002*b*) and from other expected features of electron-density maps such as a flat solvent (Wang, 1985), the presence of secondary-structural features (Terwilliger, 2001) and the presence of local patterns of density characteristic of macromolecules (Terwilliger, 2003*c*). To reduce model bias in the procedure, prime-and-switch phasing can also be used (Terwilliger, 2004). *Phenix.autobuild* uses *phenix.refine* (Afonine *et al.*, 2005) throughout this process to improve the quality of the models that are built.

Phenix.autobuild provides two complementary approaches to model building. For cases in which no model or only a preliminary model has been built, *phenix.autobuild* will construct a new model considering the main chain of any supplied models as potential coordinates. In cases where a nearly final model is available, *phenix.autobuild* can apply a rebuild-in-place approach in which the polypeptide chain is rebuilt a few residues at a time without changing the register or the overall features of the model.

The rebuild-in-place approach in *phenix.autobuild* provides a powerful method for the assessment of uncertainties in an atomic model by repetitive rebuilding of the model using different random seeds for each iteration (Terwilliger, Grosse-Kunstleve *et al.*, 2007). The variability in the coordinates of each atom in the ensemble that is created is a lower bound on the uncertainty of the position of that atom.

18.11.8. Conclusions

Advances in computational methods and algorithms have made it possible to automate the solution of many structures with *PHENIX*. However, many challenges still exist. In particular, the development of automated methods that can be applied at low resolution (worse than 3.0 Å) remains a priority. In this resolution range there are typically too few experimental data to uniquely define the macromolecular structure for automated *ab initio* model building. Thus, methods are required that rely on prior knowledge from existing macromolecular structures to permit productive automated data interpretation. These methods will need to be developed and applied for all stages of structure solution and tightly integrated to maximize the information extracted from the experimental data.

The authors would like to thank the NIH (grant GM063210) and the Phenix Industrial Consortium for support of the Phenix project. This work was supported in part by the US Department of Energy under Contract No. DE-AC02-05CH11231. RJR is supported by a Principal Research Fellowship from the Wellcome Trust (UK). We are grateful to Luc Bourhis and Marat Mustyakimov for contributions to the computational crystallography toolbox and *PHENIX*, Paul Emsley and Bernhard Lohkamp for their guidance interfacing *PHENIX* with *Coot*, the *CCP*4 developers for making the CCP4 library available for inclusion in *PHENIX*, Kevin Cowtan for providing C++ sequence-alignment code, Garib Murshudov and Alexei Vagin for making the monomer library available and our colleagues in the crystallographic community for numerous scientific discussions. We are deeply indebted to David Abrahams for numerous discussions and for accommodating our requirements when developing the Boost.Python library.

This chapter is based on a recent article published in *Acta Crystallographica Section D* (Adams, Afonine *et al.*, 2010).

Chapter 18.12. Structure determination in the presence of twinning by merohedry

T. O. Yeates and M. R. Sawaya

18.12.1. Introduction

Twinning by merohedry (see Chapter 11.7) presents challenges for structure determination because the correct intensities are not observed directly. This is a key problem, since the ultimate goal of structure determination is to arrive at agreement between the observed crystallographic quantities and the corresponding values calculated from a model. Common strategies for handling this problem at different stages of the structure-determination process are considered here. In the following discussion, it is helpful to note that, in any given strategy, one of three approaches is generally being taken. Either (i) the effects of twinning are ignored and treated essentially as a source of noise, (ii) the effect twinning has on the observed intensities is reversed – a process called 'detwinning' – in an attempt to recover the true underlying crystallographic intensities, or (iii) the effects of twinning are applied to the model in order to match the twinning present in the observed data. The following discussions apply primarily to twinning by hemihedry, in which just two domain orientations are present. For the treatment of higher forms of twinning (Yu *et al.*, 2009; Barends *et al.*, 2005) or other types of disorder (Wang *et al.*, 2005; Tsai *et al.*, 2009; Hare *et al.*, 2009), the reader is referred to the recent literature.

18.12.2. Detwinning based on observed intensities

Equation (11.7.4.1) in Chapter 11.7 describes how the observed twinned intensities arise from linear combinations of true crystallographic intensities. By inverting that system of equations, one can obtain the crystallographic intensities from the observed intensities, assuming the twin fraction α is known:

$$I(\mathbf{h}_1) = \left[(1-\alpha)I_{\rm obs}(\mathbf{h}_1) - \alpha I_{\rm obs}(\mathbf{h}_2)\right]/(1-2\alpha),$$
$$I(\mathbf{h}_2) = \left[-\alpha I_{\rm obs}(\mathbf{h}_1) + (1-\alpha)I_{\rm obs}(\mathbf{h}_2)\right]/(1-2\alpha),$$

where I are the true crystallographic intensities for two reflections $\mathbf{h}_1$ and $\mathbf{h}_2$ related by the twin operation, and $I_{\rm obs}$ are the corresponding observed intensities. The form of this equation makes it clear that the observed data cannot be detwinned when $\alpha = 1/2$ (*i.e.* perfectly twinned). When $\alpha \neq 1/2$, the crystallographic intensities can be calculated but measurement errors in the observed intensities are magnified according to the term $1/(1 - 2\alpha)$ (Fisher & Sweet, 1980; Grainger, 1969). Therefore, detwinning based on observed intensities alone tends to be problematic when the twin fraction is high. If the twin fraction is low then detwinning is robust, although in those cases the effects of twinning are the least important to consider. As a result, detwinning based only on observed intensities is not practised often. The situation is different once calculated intensities from a model become available, as discussed below.

18.12.3. Molecular replacement with twinning

Even in the case of perfect twinning, it is often possible to arrive at a correct molecular-replacement solution without taking twinning into account, as demonstrated by Redinbo & Yeates (1993). At the rotation-function stage, the effects of twinning are much like the effects of high crystal symmetry; one is attempting to detect the correct orientation of a single search model in the context of noise due to other molecules in distinct orientations within the crystal. In favourable cases such a search can be successful. At the translation-function stage, recognizing the true space-group symmetry is critical. As described in Chapter 11.7, even the correct point-group symmetry can be misclassified in cases of high or perfect twinning. Therefore, it is generally advisable to evaluate potential molecular-replacement solutions in multiple space groups consistent with the data. In practice, twinning is usually ignored throughout the molecular-replacement process (Breyer *et al.*, 1999; Contreras-Martel *et al.*, 2001; Luecke *et al.*, 1998; Redinbo & Yeates, 1993; Larsen *et al.*, 2002; Heffron *et al.*, 2006; Yuan *et al.*, 2003; Lee *et al.*, 2003; Anand *et al.*, 2007), although some workers have detwinned the data and then proceeded with molecular replacement (Rabijns *et al.*, 2001; Taylor *et al.*, 2000). In evaluating potential molecular-replacement solutions, it could be useful to consider the contributions of both domain orientations to the observed intensities; this has generally not been done.

18.12.4. Multiple isomorphous replacement and anomalous phasing with twinning

Strategies for phasing twinned data by multiple isomorphous replacement (MIR) and anomalous-scattering methods have been reviewed (Terwisscha van Scheltinga *et al.*, 2003; Dauter, 2003). To date, several successful solutions of twinned structures by MIR and anomalous phasing approaches have ignored the effects of twinning, at least during the steps of heavy-atom substructure determination and phasing (Rees & Lipscomb, 1980; Mueller, Muller *et al.*, 1999; Mueller, Schübel *et al.*, 1999; MacRae & Doudna, 2007). As noted above, such an approach effectively treats the contributions from the alternate (minor) twin domain as noise. If a correct heavy-atom substructure can be obtained, from Patterson analysis for example, that solution reflects only the heavy-atom contents of one twin domain, presumably the dominant one. Additional peaks not directly accounted for by the identified heavy-atom positions will be present in the native Patterson map in twin-related positions. Adding to the potential confusion, cross-peaks between the heavy-atom positions identified and those related by the twin operation are not present in a Patterson map. Likewise, contributions of the minor twin domain to the measured differences between native and derivative structure-factor amplitudes are ignored when estimating the best phase for the native structure factor. In favourable cases, useful heavy-atom substructures and phases can be obtained despite these serious oversimplifications. In less favourable cases, some workers have overcome twinning in MIR experiments by detwinning the native and derivative data sets, then executing isomorphous replacement with detwinned structure factors (Declercq & Evrard, 2001; Terwisscha van Sheltinga *et al.*, 2001; Hillig & Renault, 2006; Ban *et al.*, 1999). In a few cases, results indicate that detwinning the data produces maps of a quality similar to or worse than the observed twinned data (Rudolph *et al.*, 2003; Yang *et al.*, 2000; Dong *et al.*, 2001).

Figure 18.12.4.1

An illustration of how twinning operations can mix together reflections denoted F^+ and F^-. The case of space group $P4$ is illustrated. Filled squares represent a reflection $F^+_{(h1)}$ and its symmetry mates related by crystallographic operations (*i.e.* 90° rotations), while open squares represent their Friedel pairs $F^-_{(h1)}$. Filled circles represent distinct but twin-related reflections, $F^+_{(h2)}$, while open circles represent their Friedel pairs, $F^-_{(h2)}$. On the basis of the asymmetric unit shown (shaded), assuming reflections falling in the designated asymmetric unit are assigned as F^+, the twin operators (hatched lines in the *ab* plane) relate reflection $F^+_{(h1)}$ to reflection $F^-_{(h2)}$ and reflection $F^+_{(h2)}$ to reflection $F^-_{(h1)}$. Detwinning anomalous data – if such a step is deemed appropriate – therefore requires that the symmetry relationships be considered properly rather than relying on F^+ and F^- designations.

A proper treatment of the problem of phasing highly twinned data by MIR has been developed (Yeates & Rees, 1987) which takes into account the simultaneous contributions from both twin domains. The phasing of ordinary MIR data is often presented in terms of a phase circle for the native structure factor. The circle describes the requirement for the sum of the squared real and imaginary components of a structure factor to equal the observed intensity. Additional equations derived from heavy-atom information then lead to the identification of the correct point (or native phase) on this circle. In the case of twinning, taking the case of perfect twinning as an example, what is known is not an individual crystallographic intensity but the sum of two twin-related crystallographic intensities. As a result, each observed intensity leads to an equation specifying the sum of four terms: the squared real and imaginary structure-factor components of two distinct twin-related reflections. This equation is a hypersphere, and equations derived from heavy-atom information can specify the correct point on that hypersphere. This effectively identifies the correct or most probable phases for both twin-related reflections simultaneously. The utility of a proper treatment of twinned MIR data has been demonstrated in synthetic test cases (Yeates & Rees, 1987), but such treatments have not been implemented in standard crystallographic programs. It has been unnecessary in a number of successful MIR cases (Rees & Lipscomb, 1980; Declercq & Evrard, 2001; Terwisscha van Scheltinga *et al.*, 2001; Hillig & Renault, 2006; Ban *et al.*, 1999; Rudolph *et al.*, 2003; Yang *et al.*, 2000; Dong *et al.*, 2001), though there are likely to be situations where such treatment is important for success. The handling of anomalous scattering in the presence of twinning parallels that for MIR. Successful phasing has been achieved using standard programs and approaches while ignoring the presence of twinning, while more exact treatments are possible along lines similar to those advocated for MIR.

When dealing with anomalous data from twinned crystals, sometimes special care is required. It may be counterintuitive, but the twinning operation can mix together reflections carrying an F^+ and an F^- designation in a data set reduced in the correct space-group symmetry. For example, in space group $P4$, one possible choice of asymmetric region in reciprocal space would be the octant with h, k and l all non-negative (ignoring, for simplicity, the redundancy in the principal zones). Reflections recorded in this region (and those related by $P4$ rotational symmetry) would receive F^+ designations, while their Bijvoet pairs would be assigned as F^-. Reflections 123 and 213 are distinct in $P4$, and both would typically be labelled F^+ since they fall in the chosen asymmetric region. These two reflections have Bijvoet pairs $12\bar{3}$ and $21\bar{3}$, respectively, and these would be designated F^-. The twin operation (a dyad about the *xy* diagonal, for example) would mix the 123 and $21\bar{3}$ reflections together and the 213 and $12\bar{3}$ reflections together (Fig. 18.12.4.1). It is therefore important to bear in mind, particularly when contemplating detwinning data having an anomalous signal, that reflections designated F^+ and F^- in the true lower symmetry may be mixed together by the twin operation. This presents no real obstacle as long as the Bijvoet pairs are handled correctly.

Finally, although direct methods of phasing are not discussed in detail here, in cases where the resolution is high enough those methods can also be employed successfully in cases of twinning, as exemplified by the *SHELXD* program (Sheldrick, 2008).

18.12.5. Atomic refinement with twinning

If twinning is present, it must be taken into account during atomic refinement, otherwise the R values remain high. If twinning is present in combination with pseudo-crystallographic noncrystallographic symmetry (NCS), it may be possible to achieve acceptable R values at low resolution but not generally at high resolution. To account for twinning during refinement, the best approach is to use the observed intensity measurements as the target values and incorporate the effects of twinning in the calculated crystallographic quantities. Current refinement programs provide for this (Sheldrick, 2008; Adams *et al.*, 2010; Murshudov *et al.*, 1997; Brünger *et al.*, 1998). Typically, an accurate value for the twin fraction can be determined during the refinement process. Note that it is straightforward to solve for α based on a system of equations of the form given in Chapter 11.7 [equation (11.7.4.1)], where I are calculated from the model and $I_{\rm obs}$ are the observed intensities.

As noted in Chapter 11.7, the presence of twinning is sometimes difficult to detect early in structure determination based on observed intensity data alone, so atomic refinement presents an important opportunity to re-examine the possibility of twinning. As described above, the presence of twinning and an accurate value for the twin fraction can usually be obtained during refinement by comparing observed and calculated intensities. Another method of analysis, which is particularly useful for discriminating between twinning and pseudo-crystallographic NCS, is to examine $R_{\rm twin}$ (*i.e.* the R value between potentially twin-related reflections) and compare the values obtained for $R_{\rm twin}$ when it is evaluated over either observed intensity data or intensities calculated from the model (Fig. 18.12.5.1). This has been referred to as an RvR calculation (Lebedev *et al.*, 2006). The result can be especially instructive when examined as a function of resolution. For cases where twinning occurs together with NCS, the calculated and observed $R_{\rm twin}$ values may be low at low resolution, with $R_{\rm twin}$ over the calculated intensities climbing steeply at higher resolution and $R_{\rm twin}$ over the observed intensities remaining relatively low. When twinning is present in the absence of interfering NCS, the $R_{\rm twin}$ value should be nearly random for the calculated intensities but significantly lower for the observed intensities. An analysis of RvR in a survey of macromolecular structures and diffraction data in the Protein Data Bank (PDB; Berman *et al.*, 2000) has illuminated a number of cases of twinned structures (both merohedral and pseudo-

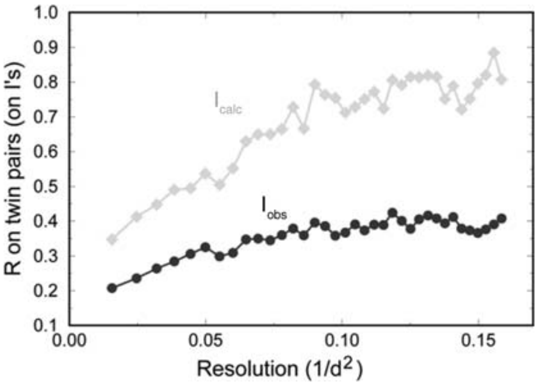

Figure 18.12.5.1
A comparison of calculated *versus* observed $R_{\rm twin}$ values indicates the presence of twinning in a crystal of alanyl-tRNA synthetase (PDB entry 1YFS; Swairjo & Schimmel, 2005). The $I_{\rm obs}$ values continue to obey the NCS/twin-law at high resolution, while the pseudo-symmetry in the $I_{\rm calc}$ values breaks down much more quickly. This particular case depicts pseudo-merohedral twinning in space group $P2_12_12_1$, allowed by nearly equal values of the unit-cell b and c dimensions.

merohedral) where the phenomenon was apparently overlooked during structure determination (Lebedev *et al.*, 2006). This survey emphasizes the importance of checking for twinning during or after atomic refinement.

One cautionary point regarding refinement is that the final R values tend to be artificially low for a twinned refinement as a purely statistical effect. Twinning produces an averaging effect on the intensities as a whole. Therefore, two data sets of twinned intensities (*e.g.* observed and calculated) will tend to differ less from each other than untwinned data sets. It has been suggested that the R values for refining a structure against perfectly twinned data are artificially lower by a factor of approximately $2^{1/2}/2$ (Redinbo & Yeates, 1993). This is in line with the related observation that the expected value of $|L|$ is 1/2 for untwinned data but only 3/8 for perfectly twinned data [see equation (11.7.6.1) in Chapter 11.7 for the definition of $|L|$]. R values must therefore be judged carefully. In particular, the statistical effect means that a drop in the R value when a problem is treated as if it is twinned is generally not good evidence for twinning. Alternative measures of discrepancy could be useful in evaluating the validity of twinned refinement in individual cases. The standard Pearson correlation (*e.g.* between $F_{\rm calc}$ and $F_{\rm obs}$) is likely to be less adversely affected by twinning than the crystallographic R value, but its utility has not been examined in practice.

An important concern when refining twinned structures is how to select test reflections when using the $R_{\rm free}$ value for cross-validation (Brünger, 1992). Selection must be made so that both members of a pair of reflections related by the twin operation are included in the test set. This is relatively simple in cases of twinning by true merohedry, but can be more complicated when dealing with pseudomerohedry.

18.12.6. Detwinning on the basis of model $F_{\rm calc}$ values

As noted above, detwinning based only on observed intensities is usually not advisable. However, once the true crystallographic intensities can be estimated based on model calculations, the situation is improved. Detwinning can be important in two situations. The primary one is to enable electron-density-map calculations. Interpretable electron-density maps require proper estimates for the true crystallographic structure-factor amplitudes ($F_{\rm obs}$). These values can be obtained effectively by detwinning, even in the case of perfect twinning, based on knowledge of the $F_{\rm calc}$ values. At least two different types of equations have been employed, which are different in detail but similar in spirit. We illustrate them in the case of perfect twinning, where the measured $I_{\rm obs} = 1/2[I(\mathbf{h}_1) + I(\mathbf{h}_2)]$ [*i.e.* $I(\mathbf{h}_1) = I(\mathbf{h}_2)$], and the calculated quantities are $I(\mathbf{h}_1)_{\rm calc}$ and $I(\mathbf{h}_2)_{\rm calc}$. In one approach (Wei, 1969), the observed intensity is simply partitioned into estimates for $I(\mathbf{h}_1)$ and $I(\mathbf{h}_2)$ according to the proportion of $I(\mathbf{h}_1)_{\rm calc}$ to $I(\mathbf{h}_2)_{\rm calc}$. This leads to

$$I(\mathbf{h}_1) = \frac{I(\mathbf{h}_1)_{\rm calc}}{\left[I(\mathbf{h}_1)_{\rm calc} + I(\mathbf{h}_2)_{\rm calc}\right]}\,2I_{\rm obs},$$

$$I(\mathbf{h}_2) = \frac{I(\mathbf{h}_2)_{\rm calc}}{\left[I(\mathbf{h}_1)_{\rm calc} + I(\mathbf{h}_2)_{\rm calc}\right]}\,2I_{\rm obs}.$$

Alternatively, one can take a least-squares approach and say that there are two equations for $I(\mathbf{h}_1)$, namely $I(\mathbf{h}_1) = I(\mathbf{h}_1)_{\rm calc}$ and $I(\mathbf{h}_1) = 2I_{\rm obs} - I(\mathbf{h}_2)_{\rm calc}$. Assuming equal estimated errors, the best choice is the average,

$$I(\mathbf{h}_1) = I_{\rm obs} + \frac{\left[I(\mathbf{h}_1)_{\rm calc} - I(\mathbf{h}_2)_{\rm calc}\right]}{2},$$

and likewise for $I(\mathbf{h}_2)$,

$$I(\mathbf{h}_2) = I_{\rm obs} + \frac{\left[I(\mathbf{h}_2)_{\rm calc} - I(\mathbf{h}_1)_{\rm calc}\right]}{2}.$$

Somewhat more complicated expressions arise when $\alpha \neq 1/2$. In either case, one obtains estimates for the true crystallographic intensities. Square roots of these quantities can then be used to calculate electron-density maps. It is critical to note that these values are useful estimates of $F_{\rm obs}$ but they are biased by the current atomic model. Therefore, when calculating electron-density maps using model-based detwinning procedures, it is important to remove model bias locally. As in other kinds of 'omit' maps, atoms in and around a particular region of interest can be removed from the model calculations before applying the detwinning procedure.

Model-based detwinning is also useful in certain atomic refinement situations. If a twinning scenario arises whose treatment is not possible using available refinement programs, model-based detwinning can be used in an iterative fashion to produce structure factors for use as target values in an otherwise ordinary refinement protocol. This strategy was used in the refinement of early cases of protein crystals twinned by hemihedry (Redinbo & Yeates, 1993) and in recent cases of protein crystals twinned by tetartohedry (Yu *et al.*, 2009; Barends *et al.*, 2005; Gayathri *et al.*, 2007).

18.12.7. Summary

Structure determination is often possible even when the only available data are from a perfectly twinned specimen. This is especially true for molecular replacement, but also in favourable cases for MIR and anomalous phasing methods. In general, at the stage where phase determination is being attempted, the available programs attempt to obtain phases (by molecular replacement or heavy-atom methods) while ignoring the presence of twinning. While this has been successful in several cases, there are opportunities for more sophisticated treatments of phase determination in the presence of twinning. Such improvements may make it possible to phase data successfully from a larger number of twinned crystals. At the stage of atomic refinement, the problem of handling twinned structures has been treated rigorously in a number of programs. The proper use of these programs makes it relatively straightforward to refine structures successfully in the presence of twinning.

The authors thank Yingssu Tsai, Regine Herbst-Irmer and George Sheldrick for helpful comments on the manuscript.

PART 19. OTHER EXPERIMENTAL TECHNIQUES

Chapter 19.1. Neutron crystallography: methods and information content

A. A. Kossiakoff

19.1.1. Introduction

Neutron and X-ray crystallography are similar in both their experimental methodologies and in the resulting information content. The principal difference between the two methods is brought about by the characteristic scattering potential of the atom types. The scattering of neutrons by material is not proportional to the atomic number, as is the case in X-ray scattering, but rather depends on the individual nuclear characteristics of each atom type. As seen in Table 19.1.1.1, these characteristics show considerably less deviation and systematic trend among the different atom types. For instance, the heavy atoms in biological material – carbon, oxygen and nitrogen – scatter with about the same magnitude as a lead or uranium atom. In addition, neutrons are scattered by the atomic nuclei, which are essentially point sources, producing diffracted intensity not attenuated by a form-factor fall-off at increasingly higher scattering angles, as is the case in X-ray diffraction (Bacon, 1975).

There are a few atomic nuclei that induce a phase change of 180° in the scattered neutron, which results in negative peaks in a neutron density map. An extremely important example of this is the hydrogen nucleus, with a scattering length of −3.7 f (1 f = 10^{-13} cm). Its isotope, deuterium, on the other hand, scatters to give positive peaks (+6.7 f). The fact that H and D atoms can be so clearly distinguished from one another has very important implications for assessing biophysical parameters, as will be discussed below.

The application of the neutron-diffraction technique, which assigns H-atom positions in proteins and differentiates between H and D atoms, has been mainly focused on structural issues in three research areas: (1) protein reaction mechanisms; (2) protein dynamics; and (3) protein–water interactions (Kossiakoff, 1985, and references therein). It must be pointed out that recent advances in nuclear magnetic resonance have made protein dynamics investigations using H/D exchange procedures much easier than similar experiments by neutron diffraction. Additionally, the advances in ultra-high-resolution X-ray crystallography, which have allowed some level of experimental determination of hydrogen atoms in proteins, have further limited the uniqueness of the neutron method. Nevertheless, a number of important structural issues that are best approached by neutron crystallography remain.

Table 19.1.1.1
Scattering lengths for atom types

Element	Atomic No.	Scattering length (f; 1 f = 10^{-13} cm)
H	1	−3.7
D	1	6.7
C	6	6.6
N	7	9.4
O	8	5.8
Mg	12	5.2
S	16	2.8
Ca	20	4.7
Hg	80	12.7
Pb	82	9.4
U	92	8.5

19.1.2. Diffraction geometries

The general experimental setup involves use of a monochromated beam, employing normal-beam (Caine *et al.*, 1976) or flat-cone geometry (Prince *et al.*, 1978). Both approaches use flat detector surfaces, and thus there is a distortion inherent in all the diffraction phenomena that increases as a function of layer line along the axis of rotation. The extent of this effect can be calculated from the experimental parameters, but, in the case of a linear detector, there is only a moderate amount of flexibility available to make the necessary adjustments. The flat-cone geometry is well suited for a linear detector, since upper-level data fall on an undistorted plane. However, such a scheme requires that the detector be adjusted to different orientations with respect to the spectrometer axis (Prince *et al.*, 1978). In the normal-beam configuration, the crystal is usually mounted on a four-circle goniometer, allowing independent rotations around the φ, χ and ω axes to cover a full sphere of reciprocal space. This method can be efficient when used with a two-dimensional area detector because of the distortion of the diffraction pattern.

19.1.2.1. *Quasi-Laue diffractometry*

A significant advance in neutron crystallography has been the development and use of modified Laue methods to collect data (Wilkinson & Lehmann, 1991; Wilkinson *et al.*, 1992; Niimura *et al.*, 1997). These methods greatly increase the available neutron flux by using the white neutron spectrum. The full white radiation cannot be used due to very high background scattering and overlap between the diffraction peaks. A reasonable compromise between maximizing intensity while minimizing the experimental problems is to limit the white radiation component to about a 20% wavelength band by employing Ti–Ni multiple-spacing multilayers (Niimura *et al.*, 1997). In practice, the use of the Laue method in X-ray diffraction allows most of the reciprocal space to be recorded in one crystal setting. The quasi-Laue application requires several settings, depending on the neutron intensity distribution $I(\lambda)$ and the crystal symmetry. Data processing can be done using Laue software modified for neutron data.

19.1.3. Neutron density maps – information content

Fig. 19.1.3.1 illustrates several types of structural information derived from neutron density maps. Fig. 19.1.3.1(*a*) shows a well ordered tyrosine ring in the 1.4 Å structure of the protein crambin (Teeter & Kossiakoff, 1984). It can be seen that the ring hydrogen-atom locations are in positions of negative density. These peaks appear to be slightly displaced from their true

(*a*) (*b*)

Figure 19.1.3.1
Information content in neutron density maps. (*a*) A well ordered tyrosine ring in the 1.4 Å refined structure of crambin (Teeter & Kossiakoff, 1984). (*b*) $D_2O - H_2O$ difference density map of a hydrogen-bonding network in trypsin: Gln30 Oε1–Ser139 D_{γ}, Ser139 O_{γ}–W301, W301–Tyr29 DO. Water density and H/D exchange density shown.

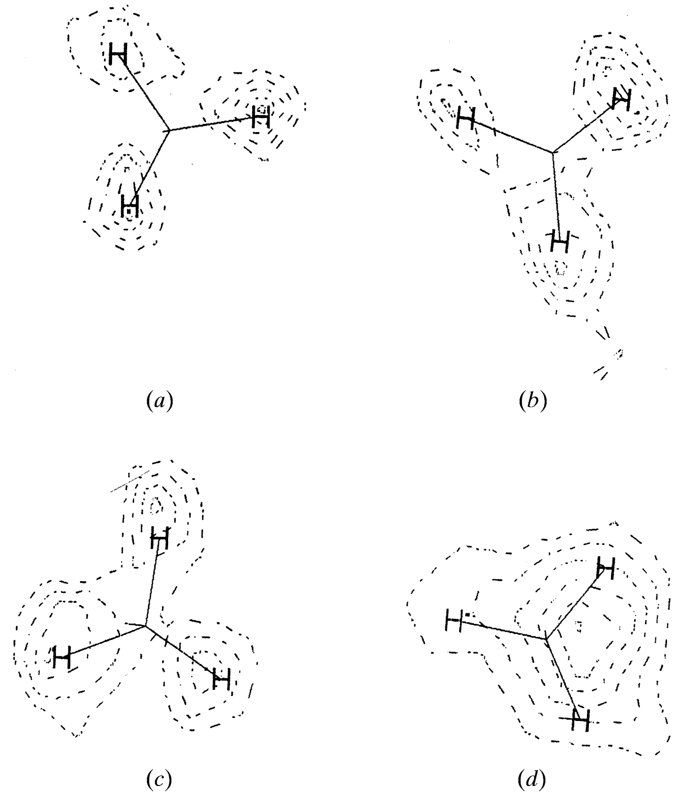
positions, because the map is not at atomic resolution. At 1.4 Å, a portion of the negative peak of the hydrogen overlaps the positive peak of the ring carbon, effectively cancelling density between the atoms and giving the illusion that the peak has been translated. The hydroxyl deuterium orientation is readily determined by its position in positive density.

Use of $D_2O - H_2O$ neutron difference maps provides a high level of stereochemical information (see below) (Kossiakoff *et al.*, 1992; Shpungin & Kossiakoff, 1986). Fig. 19.1.3.1(*b*) displays a network of three hydrogen bonds involving three side-chain types and an occluded water. With knowledge of the heavy atoms alone, it is not possible to define the donor/acceptor character of any of the side chains, because they can act in either capacity, as can the water. The assignments can be made unambiguously from the $D_2O - H_2O$ density, as can the orientation of the water molecule. These maps have allowed detailed analysis of hydroxyl orientations in protein molecules (Kossiakoff *et al.*, 1990; McDowell & Kossiakoff, 1995).

Neutron diffraction is an ideal method for investigating methyl-group conformation, because it allows direct observation of hydrogen-atom positions (Fig. 19.1.3.2) (Kossiakoff & Shteyn, 1984). Although methyl groups in proteins are not held in fixed positions, but spin rapidly around their rotor axes, the time-averaged character of the diffraction experiment establishes the low-energy conformer and the degree of disorder. Accurate methyl-group analysis requires relatively higher resolution (1.5 Å or better) than characterizing other structural features.

19.1.4. Phasing models and evaluation of correctness

Neutron diffraction does not lend itself to the multiple isomorphous phasing approach. This is because the range in atomic scattering power is much narrower than for the X-ray case. There are a few relatively rare isotopes where a significant anomalous effect exists; however, they are not adequate for getting primary phasing information (Schoenborn, 1975). In practice, the initial phasing model has to be derived from the X-ray-determined structure. This is done by applying the appropriate neutron scattering lengths to the refined X-ray coordinates (Norvell & Schoenborn, 1976). Thus, at least in the early stages of analysis, the neutron model relies heavily on the accuracy of the X-ray structure. The importance of an accurate phasing model is borne out by the fact that in several investigations the phasing models were not accurate enough to allow the structure to be refined successfully.



(*a*) (*b*)

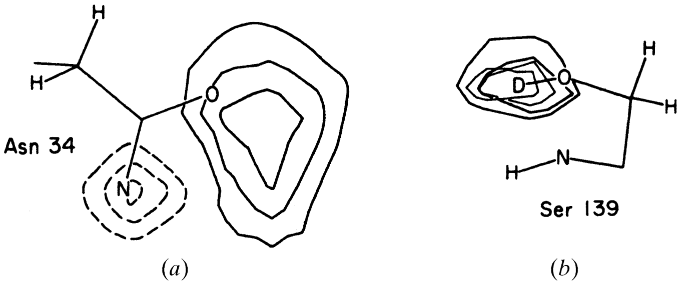
(*c*) (*d*)

Figure 19.1.3.2
Sections of a neutron difference Fourier map showing methyl hydrogen densities for several representative methyl groups. No phasing information about the methyl hydrogens was included in the model; therefore, hydrogens should appear in the difference map at their true positions but at reduced density (~ half weight). The groups shown are: (*a*) Ala24, (*b*) Thr21, (*c*) Thr28, and (*d*) Ala45.

19.1.5. Evaluation of correctness

It is an important first step in the structural analysis to determine the quality of the phases derived from the X-ray structure (Kossiakoff, 1983). Several methods have been used. Using the initial phasing model, the most powerful tests examine an unbiased neutron Fourier map for the appearance of features that are independent of the model. The presence or absence of these features, especially those resulting from the scattering of hydrogen and deuterium atoms, is the most reliable measure of the phasing model. One such test is to evaluate the appearance of the water structure, *i.e.*, the water molecules hydrogen-bonded to the surface of the protein. The water molecules observed in the X-ray analysis are excluded from the neutron-phasing model. The test is applied in cases where the crystals have been soaked in D_2O. The peaks in the neutron density map that correspond to the strongly coordinated water-molecule positions owe their existence solely to the neutron data and phasing model. Even at an early stage, because of the large neutron-scattering potential of D_2O, many of these tightly bound waters found in the X-ray structures should also be observable in the neutron density map.

Another aspect to test phasing reliability is the ability to identify the orientation of side-chain amide groups of asparagine and glutamine. The difference in neutron scattering between O



(*a*) (*b*)

Figure 19.1.5.1

Difference map of Asn34 in the trypsin structure. (*a*) In a protein X-ray analysis, the difference in scattering intensity between O and NH_2 is much too small to be detected. In contrast, the neutron-scattering magnitudes of oxygen and nitrogen (5.8 f *versus* 9.4 f) are quite dissimilar, and there is additional scattering at the nitrogen site from the two bound deuterium atoms. The resulting differential is over 350%, quite large enough to be detected for well ordered side chains. The nitrogen and oxygen positions shown are from the X-ray model. The difference density indicates that the orientation of the nitrogen and oxygen atoms is incorrect and should be rotated by 180° around the C_β–C_γ bond. (*b*) Difference map for Ser139. On well ordered hydroxyl side chains, the orientation of deuterium atoms can sometimes be assigned.

and the two deuteriums and the Nδ2 (5.8 f *versus* 22.6 f) is large enough to be detectable in the Fourier map when these groups are well ordered (Fig. 19.1.5.1). The use of unexchangeable hydrogens for evaluation is considerably more complicated, despite the fact that they constitute about one-half the total number of atoms in the molecule. The difficulty arises from the negative scattering character of the hydrogens, which displaces their apparent positions in the Fourier map from the true positions and, coupled with their short bond lengths, complicates the interpretation of the results. Additionally, it has been shown that small errors in positional and thermal parameters of the parent atoms can further complicate the identification of hydrogen-atom positions (Kossiakoff & Spencer, 1981).

19.1.6. Refinement

The methodologies employed to refine neutron data are essentially the same as those used in most X-ray studies. These include real-space (Hanson & Schoenborn, 1981; Norvell & Schoenborn, 1976; Schoenborn & Diamond, 1976), reciprocal-space (Bentley & Mason, 1980; Phillips, 1984; Wlodawer & Hendrickson, 1982; Wlodawer & Sjolin, 1981) and restrained difference-map refinement (Kossiakoff & Spencer, 1980, 1981). A joint refinement technique in which the neutron and X-ray data are refined simultaneously has been developed (Wlodawer & Hendrickson, 1982). In addition to the normal difficulties encountered in the refinement of any protein structure, there are several that are peculiar to the neutron-diffraction technique. These special problems arise from the close proximity of hydrogen atoms to their parent atoms, coupled with the effects of the negative scattering length of the hydrogen atoms. Potential problems exist when the difference density generated from positional errors of one atom overlaps an adjacent atom site. The situation is further complicated by the fact that, because of its negative scattering length, an error in a hydrogen-atom position is minimized by moving the atom down the gradient, that is, in the opposite direction to that required for correcting parent-atom positions. To evaluate the extent of this problem in refinement, a test was devised using a 2.2 Å data set (Kossiakoff & Spencer, 1981). The coordinates of the protein trypsin were perturbed by a varying, but known, amount from their ideal positions. It was determined that, in general, convergence towards the true coordinate could be obtained when the coordinate errors were less than 0.3 Å; however, if the parent atom (an atom with one or more hydrogens attached to it) was displaced by more than 0.6 Å from its correct position, the effect of neighbouring hydrogens rendered the calculated shifts inaccurate. The results of this study support the observations of other investigators that it is absolutely crucial that the starting phasing model be of high quality, because the range of convergence of a neutron analysis is relatively small.

19.1.7. $D_2O - H_2O$ solvent difference maps

$D_2O - H_2O$ solvent difference maps provide an unbiased method for identifying water molecules and exchangeable hydrogens (Kossiakoff *et al.*, 1992). For several years, the large difference in the scattering characteristics of neutrons by H_2O compared to D_2O has been effectively exploited by using density matching and exchange labelling in small-angle neutron-scattering experiments. This difference can likewise be exploited in neutron protein crystallography to determine the detailed structural characteristics of protein hydration through the calculation of solvent difference maps (Shpungin & Kossiakoff, 1986; Kossiakoff *et al.*, 1992). In practice, such maps are obtained by comparing the changes in diffracted intensities between two sets of data – one obtained from a crystal having H_2O as the major solvent constituent, and a second where D_2O is the solvent medium. To a good approximation, the protein-atom contributions to the scattering intensities in both data sets are equal and cancel, but since H_2O and D_2O have very different scattering properties, their differences are accentuated to reveal an accurate and nearly unbiased representation of the solvent structure.

The features of a solvent difference map of this type are not as affected by errors in the phasing model as conventional difference Fourier maps. In addition, there are refinement procedures that can be applied to them that lead to significant enhancement in signal/noise discrimination. The basic feature of the method is a set of density-modification steps based on the fact that a considerable amount of information about the density distribution of the crystallographic unit cell is known. For instance, it is known that the region of the unit cell occupied by protein atoms should be featureless in solvent maps. It can also be assumed that, as an approximation, solvent regions further than 4 Å from the protein surface have bulk solvent characteristics and can be treated as a constant density region. Combining these two regions gives about 50–60% of the total volume of the unit cell.

Knowledge of the density content of such a large percentage of the unit cell places a strong constraint on the overall character of the Fourier transform, a fact that can be used to improve the quality of the experimentally determined phases

19.1.8. Applications of $D_2O - H_2O$ solvent difference maps

19.1.8.1. *Orientation of water molecules*

In the case of a highly ordered water in a $D_2O - H_2O$ difference map, the oxygen scattering components will cancel (having identical locations and scattering potential), but because H and D have very different scattering properties (H = −3.8 f, D = +6.7 f), large peaks will be found in the map at the D − H positions. Consequently, these ordered waters can usually be oriented with reasonable accuracy in maps better than 2.0 Å resolution (see Fig. 19.1.3.1*b*).

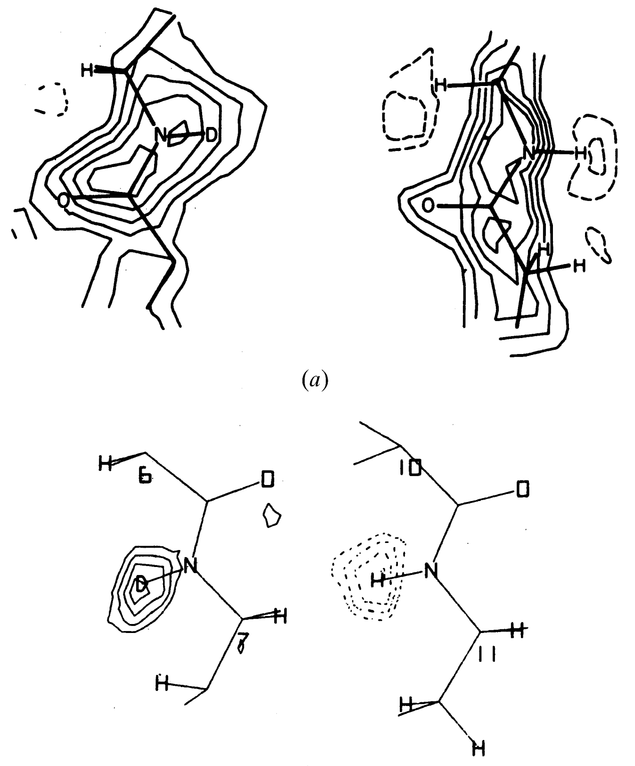


Figure 19.1.8.1
Sections of neutron density maps taken in the plane of the peptide group. (*a*) $2F_o - F_c$ maps showing an example of an exchanged and unexchanged amide peptide group. (*b*) $D_2O - H_2O$ difference density map showing the same.

19.1.8.2. H/D exchange

Fig. 19.1.8.1 shows examples of density around exchanged and unexchanged amide peptide sites. The density in Fig. 19.1.8.1(*a*) is characteristic of $2F_o - F_c$ Fourier maps; the D is in positive density, extending off the peptide nitrogen, and the H is represented by negative density, separated and translated off the nitrogen. Fig. 19.1.8.1(*b*) shows a $D_2O - H_2O$ density map at the same resolution (2.0 Å). Assignment of H/D character is unambiguous, and it is possible to evaluate partial exchange properties more reliably.

Chapter 19.2. Electron diffraction of protein crystals

W. Chiu

19.2.1. Electron scattering

When an electron interacts with a free atom, it is simultaneously attracted to the nucleus because of the nuclear positive charge and repelled by the electrons of the atom. An electron scattering event is a composite of these forces (Hirsch *et al.*, 1977). Mathematically speaking, an electron 'sees' the potential function of the atom, which can be approximated as a 'screened Coulomb potential function'. This function is often referred to as a mass-density function and is analogous to the electron-density function in the case of an X-ray photon, which is scattered only by the electrons of an atom.

Because of the strong interactions between an electron and an atom, the scattering cross section of an atom is much higher for electrons than it is for X-rays. For a 100 keV electron, it is about 10^4 times greater than for an X-ray. For every single electron scattering event of a carbon atom, there is more than a 60% probability that the electron will lose part of its energy, which is called inelastic scattering. The energy lost is primarily in the range 10 to 20 eV, which is sufficient to induce excitation and ionization of the atoms upon irradiation (Isaacson, 1977). This energy transfer to a molecule results in breakage of chemical bonds and mass migration of broken molecular fragments.

19.2.2. The electron microscope

An electron microscope is conceptually analogous to a light microscope. It consists of an electron source, condenser lenses, an objective lens, projector lenses and a camera recorder. Because of the electronegative property of the electron, it is possible to fabricate magnetic and electrostatic lenses to focus electrons to near atomic resolution. The most critical lens in an electron microscope is the objective lens, which forms the first diffraction pattern at its focal plane and the first image at its image plane. An electron diffraction pattern is the same as an X-ray diffraction pattern, containing only the amplitude information of the structure factor, whereas an electron image contains both the amplitude and phase information of the structure factor (Unwin & Henderson, 1975).

The condenser lens is used primarily to control the beam diameter and the flux of the electrons irradiating the specimen, whereas the projector lenses are used to magnify either a diffraction pattern or an image in a broad range. The camera length in an electron microscope is adjustable, ranging from 0.2 to 2.5 m, and allows the recording of diffraction patterns with Bragg spacings from hundreds to a fraction of an ångstrom. The magnification of an image spans from a hundred to a million times. Magnification is not a limiting factor for image resolution, however, and is typically set between 40 and 80 000 times for protein electron crystallography. The most important factors that affect the instrumental resolution are the coherence of the incident electron beam, the chromatic and spherical aberrations of the objective lens, the electrical stability of the electron gun and the objective lens, and the mechanical stability of the specimen stage (Chiu & Glaeser, 1977). In general, almost all modern electron microscopes are capable of resolving a lattice spacing of 2.4 Å in a thin gold crystal. The biological structure resolution in an image of a protein crystal has not reached the instrumental resolution because of many factors related to radiation damage of the specimen. Improvements in experimental and computational methods, however, have made it feasible to image protein crystals beyond 3.7 Å resolution (see below).

The range of electron energy used in an electron microscope is between 20 and 1000 keV, which corresponds to wavelengths of 0.086–0.0087 Å. Any single microscope is built and optimized for a narrow energy range because of the complex design of a highly stable electron gun. The instrument most commonly used for molecular-biology structure research operates in the range 100 to 400 keV. Choosing the most useful electron energy is based on the desired resolution and the specimen thickness. The thicker the specimen, the higher the energy that should be used in order to avoid dynamical scattering effects and to have a sufficient depth of field, so that the electron scattering data can be interpreted with a single scattering theory. Theoretically, the specimen thickness should not exceed about 700 Å if the targeted resolution is 3.5 Å with a 400 kV microscope. Beyond this specimen thickness, the phase error of the structure factors might approach 90° at that resolution. An added advantage of using higher electron energy is to reduce the chromatic aberration effect, resulting in a better-resolved image (Brink & Chiu, 1991).

There are different types of electron emitters, including tungsten filaments, LaB_6 crystals and field emission guns, all of which use different mechanisms to generate the electrons. The field emission gun produces the brightest, most monochromatic beam. The high brightness can allow the electrons to be emitted as from a point source to irradiate the specimen with a highly parallel (*i.e.* a highly spatially coherent) illumination. The benefit of high spatial coherence is the preservation of high-resolution details in the image, even though the defocus of the objective lens is set very high in order to have low-resolution feature contrast (Zhou & Chiu, 1993). Thus, a field emission source is the best choice for high-resolution data collection.

The recording medium of an electron microscope can be an image plate, a slow-scan charge-coupled-device (CCD) camera, or photographic film. Because of their broad dynamic range and high sensitivity, both the CCD camera and the image plate are best suited for recording diffraction patterns (Brink & Chiu, 1994). However, for high-resolution image recording – when the recorded area, pixel resolution, signal-to-noise ratio and the modulation transfer function characteristics must be considered – photographic film is the optimal choice (Sherman *et al.*, 1996).

19.2.3. Data collection

19.2.3.1. Specimen preparation

An electron microscope column is kept at a pressure of $<10^{-6}$ Torr (1 Torr = 133.322 Pa). Because a thin protein crystal loses its crystallinity if dried in a vacuum, its hydration can be maintained by embedding it in a thin layer of vitreous ice, glucose, or other small sugar derivatives (Unwin & Henderson, 1975; Dubochet *et al.*, 1988). The effectiveness of these preser-

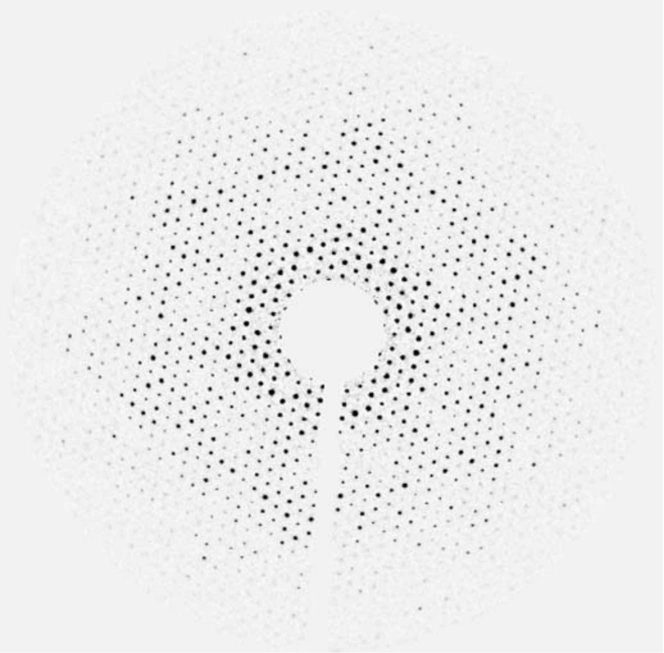

Figure 19.2.3.1

Electron diffraction pattern of trehalose-embedded bacteriorhodopsin, with Bragg reflections extending to 2.5 Å. The unit-cell parameter of this 45 Å-thick membrane protein crystal is 62.5 × 62.5 Å arranged in a $p3$ two-dimensional space group. The raw diffraction pattern was recorded on a Gatan 2k × 2k CCD camera with 300 kV electrons in a JEOL 3000 electron cryomicroscope equipped with a field emission gun and a liquid-helium (4 K) cryoholder. The pattern displayed has been contrast-enhanced using radial background subtraction. A central beam stop was used to prevent saturation of the detector but has blocked off some reflections. $R_{\rm sym}$ for the Friedel-symmetry-related reflections (about 290 pairs) was computed to be about 5%. (Courtesy of Drs Yifan Cheng and Yoshinori Fujiyoshi at Kyoto University.)

vation methods is evidenced by the high-resolution diffraction orders (out to at least 3 Å) from properly embedded protein crystals (Fig. 19.2.3.1). Since the high-resolution reflections come mostly from the protein, their diffraction intensities are largely independent of the embedding medium. However, the low-resolution diffraction intensities can be affected by the embedding medium because different media have different scattering densities relative to the protein. For any new crystal, any of the embedding media mentioned above can be used for high-resolution structural studies.

19.2.3.2. Radiation damage

All protein crystals are prone to radiation damage caused by inelastically scattered electrons (Glaeser, 1971). This physical process is easily seen in the fading of electron diffraction intensities of a protein crystal as the accumulated doses increase. The consequence of damage is a preferential loss of the high-resolution information. Radiation damage is a dose-dependent process and cannot be reduced by adjusting the dose rate (flux) of the irradiating electrons. The strategy used to minimize the damage is to record the diffraction or image data from a specimen area that has not been previously exposed to electrons for purposes of focusing or other adjustments (Unwin & Henderson, 1975). This is called a minimal or low-dose procedure. In addition, keeping a specimen at low temperature (<113 K) allows it to tolerate a higher radiation dose (by a factor of about 4 to 6) before reaching the same extent of damage as at room temperature (Hayward & Glaeser, 1979). It has been shown that damage reduction is minimal below liquid-nitrogen temperature (Chiu *et al.*, 1981). However, there have been some impressive results using the electron cryomicroscope to study membrane protein crystals kept at liquid-helium temperature (4 K) (Kühlbrandt *et al.*, 1994; Kimura *et al.*, 1997; Miyazawa *et al.*, 1999).

19.2.3.3. Other technical factors

In order to record a three-dimensional data set, the crystals have to be tilted to different angles with respect to the direction of the electron beam. In a typical electron microscope, the highest angle to which the specimen stage can be tilted is about ±60°. Consequently, there is a missing set of data beyond the highest tilt angle, which corresponds to no more than 15% of the entire three-dimensional volume. Because of the radiation damage, a single diffraction pattern or a single image per crystal is usually recorded (Henderson & Unwin, 1975). The quality of a crystal is easily judged by its electron diffraction pattern as captured from a CCD camera during data collection. Evaluating the ultimate quality of images, however, takes more time and requires extensive computational analysis.

There are two major technical problems that often limit the data quality, even though a crystal is highly ordered (Henderson & Glaeser, 1985). One is the flatness of the crystal, and the other is the beam-induced movement or charging of the crystal. The effects of both problems become more prominent when the crystals are tilted to high angles. These effects tend to blur the diffraction spots, resulting in loss of high-resolution data (Brink, Sherman *et al.*, 1998). There are many ways to overcome these technical handicaps. For instance, the type of microscope grid chosen or the method of making the carbon support film is critical for reducing the wrinkling of the crystals (Butt *et al.*, 1991; Glaeser, 1992; Booy & Pawley, 1993). The use of a carbon film, which is a good conducting material, to support the protein crystal appears to reduce specimen charging (Brink, Gross *et al.*, 1998). It has been suggested that using a gold-plated objective aperture is effective in reducing specimen charging by generating a stream of secondary electrons to neutralize the positive charges that have built up on the specimen, which thus acts like an aberration-inducing electrostatic lens. Empirically, irradiating the microscope grid before depositing the specimen also reduces the charging (Miyazawa *et al.*, 1999). All these technical problems that can hamper progress in the completion of the structure determination have gradually been identified and resolved. However, more convenient and more robust experimental procedures for reducing these effects further are desirable in order to enhance the efficiency of data collection.

19.2.4. Data processing

19.2.4.1. Data sampling

The principle of three-dimensional reconstruction is based on the central section theorem, which states that the experimental or computed projected diffraction pattern of a three-dimensional object is a plane that intersects the centre of the three-dimensional Fourier space in the direction normal to the direction of the projection (DeRosier & Klug, 1968). Because of the crystallographic symmetry inherent in a protein crystal, only a portion of the entire three-dimensional Fourier space, equivalent to an asymmetric unit of the crystal unit cell, is needed for the reconstruction. The structure factors of a three-dimensional crystal are localized in the three-dimensional reciprocal lattice, whereas the structure factors of a two-dimensional crystal are

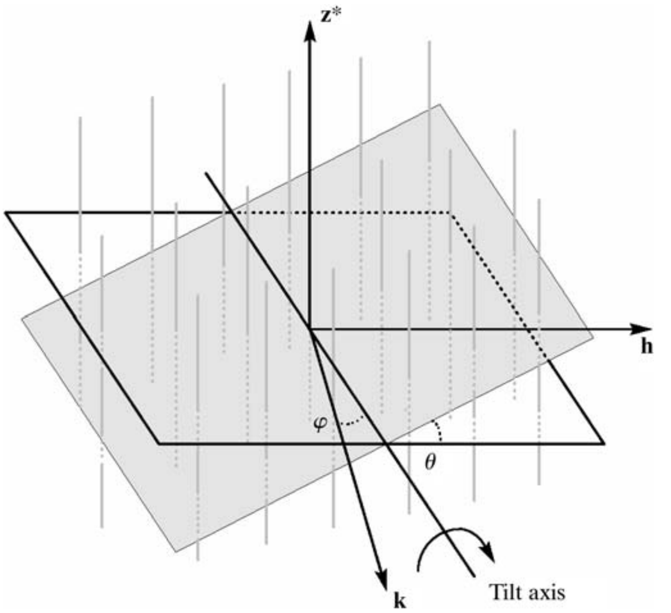

Figure 19.2.4.1
Schematic diagram of data distribution in Fourier space for a two-dimensional crystal. Both the amplitudes and phases of the structure factors are distributed along the lattice lines passing through the (h, k) projection plane. The sectional plane shown denotes data from a crystal tilted at a certain angle (φ), and its tilt axis has an inclined angle (θ) with respect to one of its crystallographic axes. (Courtesy of Dr Jaap Brink at Baylor College of Medicine.)

distributed continuously along the lattice lines, each of which passes through the reciprocal lattice in the zero projection plane (Fig. 19.2.4.1) (Henderson & Unwin, 1975). The assignment of z^* for each observation (h, k, z^*) along the lattice line is determined from the tilt angle and direction of the tilt axis for each image (Shaw & Hills, 1981). In general, the three-dimensional data set is initially built up from low-angle data and is gradually extended to the high-angle data. The angular parameters for each observed reflection are iteratively refined among one another within the whole data set. The required accuracy of these angular determinations depends on the thickness of the crystal and also on the desired resolution (Prasad *et al.*, 1990). For instance, the angular accuracy has to be $< 0.1°$ for 3.5 Å data in a 100 Å-thick crystal. The sampling of the data along the lattice line is generally about $\frac{1}{4}$ the thickness of the crystal (Henderson *et al.*, 1990). The data points are not evenly sampled along the lattice lines; they must be fitted into continuous and smoothly varying functions within the constraint of the crystal thickness. These functions are interpolated onto a periodic lattice, so that its inverse Fourier transform can be computed to reconstruct the three-dimensional mass-density function of the object.

19.2.4.2. Amplitudes and phases

An electron-microscope image contains both the amplitudes and phases of the structure factors. The basic premise of the current image-reconstruction scheme assumes that the image intensity can be related to the structure factor linearly and can be retrieved by the Fourier transform of the image intensities. However, the structure factors, $F(S)$, are influenced by several instrumental factors, as shown in equations (19.2.4.1)–(19.2.4.3) below, whose parameters need to be determined for each image.

$$F^2_{\rm obs}(S) = [F(S){\rm CTF}(S)E(S)]^2 + N^2(S), \qquad (19.2.4.1)$$

$${\rm CTF}(S) = -\{(1-Q^2)^{1/2}\sin[\gamma(S)] + Q\cos[\gamma(S)]\} \text{ and } \qquad (19.2.4.2)$$

$$\gamma(S) = \pi[(-C_s\lambda^3S^4)/2 + \Delta z\lambda S^2], \qquad (19.2.4.3)$$

where $F_{\rm obs}$ is the structure factor computed from the electron cryomicroscopic images, F is the true structure factor, CTF is the contrast-transfer function, E is the product of many decay functions due to the electron optics and specimen movement, N is the background noise contributed by a variety of physcial effects, S is the spatial frequency, Q is the fraction of amplitude contrast, C_s is the spherical aberration coefficient of the objective lens, λ is the wavelength and Δz is the image defocus.

In practice, it is tedious to determine all the parameters in these equations from images in order to make corrections to the amplitudes of the structure factors. In the case of crystals, the amplitudes of the structure factors can simply be obtained directly from the electron diffraction intensities, which are free from any of the above factors (Unwin & Henderson, 1975). The computational procedure used to calculate the diffraction spot intensities is similar to that used to measure an X-ray diffraction pattern (Baldwin & Henderson, 1984; Brink & Wei Tam, 1996). The quality of the diffraction intensity measurement is evaluated from the value of $R_{\rm sym}$ for Friedel-related reflections. The best data have $R_{\rm sym}$ less than 0.04. The consistency of the diffraction intensities among different patterns from different crystals is judged from $R_{\rm merge}$, which is generally 0.15–0.25 (Kimura *et al.*, 1997; Nogales *et al.*, 1998). Fig. 19.2.4.2 is an example of the diffraction intensity for two lattice lines computed from bacteriorhodopsin crystals. The phases of the structure factors are computed from images.

In addition to the instrumental factors given in equations (19.2.4.1)–(19.2.4.3), however, images are generally imperfect because of bending of the crystal, specimen preparation, or magnification variations across an image. The consequence of these imperfections is a reduction of the signal-to-noise ratio in high-resolution reflections. A computational procedure called ‘unbending’ has been devised, which in effect fixes the image imperfection by finding the unit-cell deviation vectors and straightening them by interpolation (Henderson *et al.*, 1986). The effect of the instrumental factors is the modulation of the phases by the oscillating function CTF(S), as shown in equations (19.2.4.1)–(19.2.4.3). The result is that the phases flip by π at different frequencies, depending on the defocus setting (Erickson & Klug, 1970). In addition, there is a phase shift caused by a combination of factors, including lens astigmatism, beam tilt and specimen height variation in a tilted position. All of these factors have to be corrected for each micrograph before merging the phases of the reflections from different micrographs to a common phase origin. The determination of the phase origin is performed by phase residual difference minimization or correlation matches among different micrographs (Amos *et al.*, 1982; Thomas & Schmid, 1995). Intensities and corresponding phases of two lattice lines are shown in Fig. 19.2.4.2. The fitted curves show the matches among the data points, each of which is from a different image or from different symmetry-related reflections from the same image.

In electron crystallography, the correctness of the phases can be evaluated by the self-consistency of the merged data sets and also by the phase residual difference of the symmetry-related reflections according to the two-dimensional plane-group symmetry. For two-dimensional crystals, there are only 17 possible plane groups (Amos *et al.*, 1982). As in the case of a three-dimensional crystal, the plane group is determined from the symmetry of the phases, the unit-cell parameters and the pattern of forbidden reflections. The plane-group assignment can be confirmed by the phase equivalence of symmetry-related reflections. Furthermore, the reliability of the map can be judged

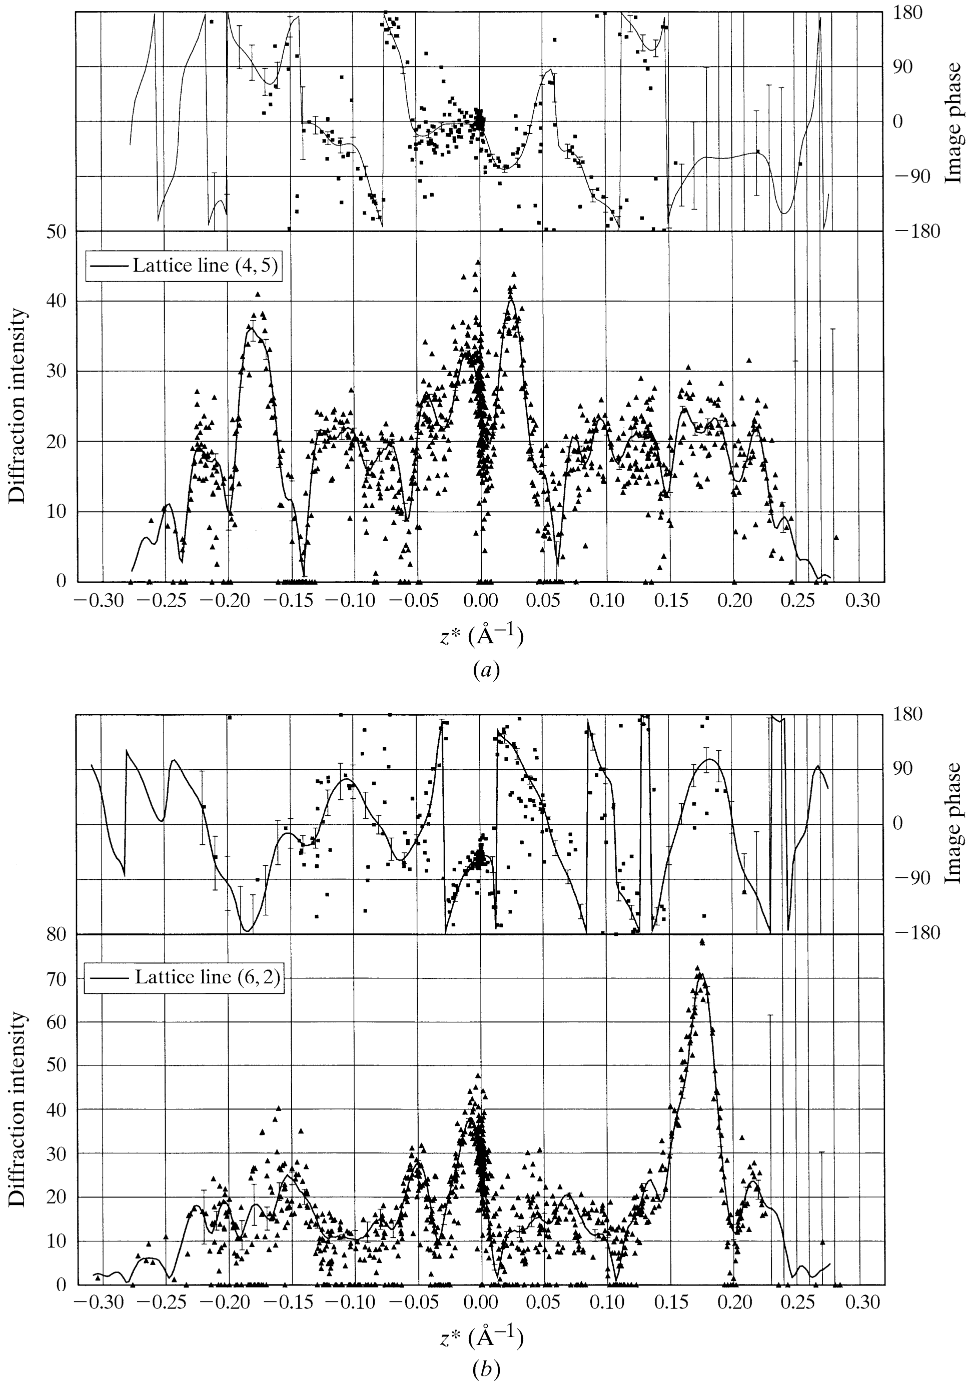

Figure 19.2.4.2

Experimental intensities from electron diffraction patterns and phases from images of bacteriorhodopsin, recorded from tilted crystals in an electron cryomicroscope. Fitted curves for two representative lattice lines are shown: (*a*) (4, 5, z^*) and (*b*) (6, 2, z^*) (Courtesy of Drs Terushisa Hirai and Yoshinori Fujiyoshi at Kyoto University.)

by the figure of merit of the phases, computed from the phase probability distribution function of the observed reflections.

19.2.4.3. 3D map

The three-dimensional (3D) map is computed from the amplitudes and phases at the resolution defined by the data (Henderson & Unwin, 1975). The resolution reported for the structure is defined by the observed reflections in the images. Owing to the missing data at high tilt angles, the reconstruction normally has a lower resolution in the direction of the electron beam than in the direction normal to it. As a result, many of the initial low-resolution structures appear stretched out along the vertical direction. The interpretation of the 3D map derived from electron crystallography is similar to that of X-ray crystallography. Often, the initial map is reported at about 7 Å, where some of the α-helices can be interpreted. With an improved map of about 3.5 Å, the polypeptide backbone is traced and some of the bulky side chains are recognized. Fig. 19.2.4.3 shows a chain tracing of a tubulin crystal (Nogales *et al.*, 1998).

19.2.4.4. Refinement

In order to arrive at a correct mechanistic model for the protein, an accurate atomic structure is needed. So far, in electron crystallography only bacteriorhodopsin has been refined (Grigorieff *et al.*, 1996). A common criterion used in X-ray crystallography to evaluate the progress of refinement is based on

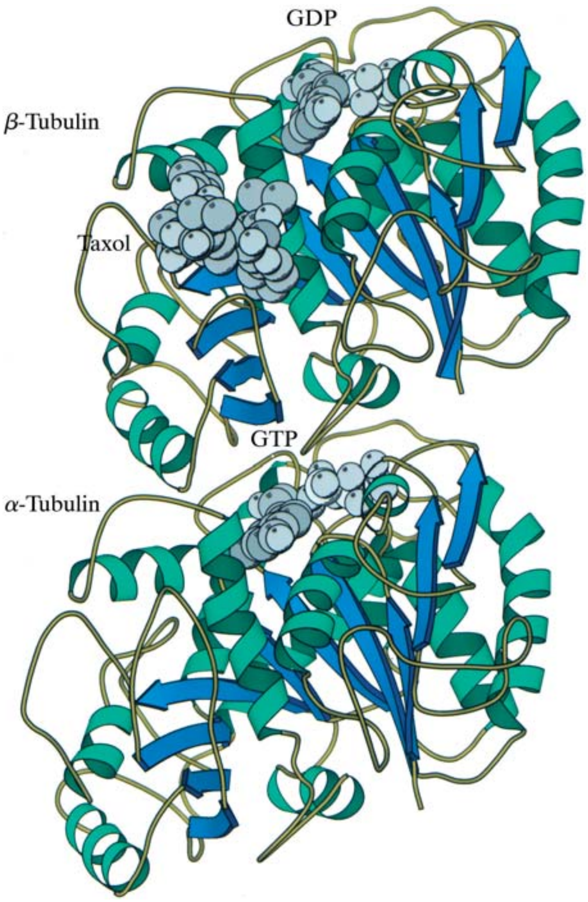

Figure 19.2.4.3
Ribbon diagram of a tubulin dimer, whose structure has been solved to 3.7 Å resolution. GTP, GDP and taxol are shown as CPK models, with GDP at the top, bound to β tubulin, and GTP in the middle, bound to the α subunit. This is the view as seen from inside a microtubule, with the plus end at the top. (Courtesy of Drs Eva Nogales and Kenneth Downing at the Lawrence Berkeley National Laboratory, University of California, Berkeley.)

the free R factor, which measures the agreement between the model and a part of the experimental data not included in the refinement process. In electron crystallography, the phases are measured independently from images and hence are not refined. Therefore, they can be used as a 'free phase residual,' which is analogous to the free R factor, to assess the progress of refinement. The refined structure would result in improved peptide geometry, increased accuracy of the coordinates of the polypeptide backbone and of the amino-acid side chain residues, and improved temperature factors of the residues.

19.2.5. Future development

Electron crystallography has proven to be a high-resolution structural tool for two-dimensional protein crystals, to the point where the polypeptide backbone can be traced and atomic coordinates derived. Needless to say, there is still much to be learned about how to make highly ordered two-dimensional crystals from either membrane or soluble proteins. Research in this direction is critical for the growth of electron crystallography. Recent results have promoted optimism; there has been an increase in the number of membrane proteins crystallized into two-dimensional arrays from which at least 6 to 8 Å structures can be obtained (Walz *et al.*, 1997; Auer *et al.*, 1998; Zhang *et al.*, 1998; Unger *et al.*, 1999).

In the most recent high-resolution structural study of tubulin, a 3.7 Å map was obtained from 100 electron diffraction patterns and 150 electron images. Effectively, this structure was the result of a computational average of about one million tubulin dimers. It took six years to determine the structure from the time when the first high-resolution crystal structure was reported (Downing & Jontes, 1992; Nogales *et al.*, 1998). All the experimental and computational procedures were basically the same as those developed for bacteriorhodopsin (Henderson *et al.*, 1990). An obvious future development in protein electron crystallography would be aimed at improving the throughput of the structural determination. This entails a search for better solutions to some of the technical problems mentioned above as well as the introduction of automation in both data collection and processing.

Finally, another potentially exciting aspect of electron crystallography is the ability to detect charged residues from the high scattering differences between neutral and charged atoms. This physical property may make electron crystallography a unique method for detecting the ionization state of the amino-acid residues in proteins (Mitsuoka *et al.*, 1999). Furthermore, there is also a good prospect of extending the structure close to 2 Å resolution, as the next generation of electron cryomicroscope will be equipped with a field emission gun operated at 300 keV, a liquid helium cryo-specimen stage and an energy filter. This combination of instrumental features is likely to bring electron crystallography a step closer to its ultimate potential for structural biology research at the atomic level.

Research has been supported by RR002250. I thank Drs Jacob Brink, Michael Schmid, Karou Mitsuoka and Ken Downing for helpful comments on the manuscript.

Chapter 19.3. Small-angle X-ray scattering

H. Tsuruta and J. E. Johnson

19.3.1. Introduction

Mechanistic biology is frequently confronted with an experimental paradox. High-resolution structures are required to develop a chemical description of macromolecular interactions, but the processes themselves are dynamic and not amenable to high-resolution methods. Chemists and molecular biologists have been successful in generating homogeneous components and entire complex systems that are amenable to crystallization and high-resolution analysis. If the dynamics of the systems are small, as in the case of some enzymes and electron-transfer reactions, time-resolved studies can be performed in the context of the crystal lattice using Laue diffraction (Moffat, 1997; Genick *et al.*, 1997; Srajer *et al.*, 1996). If the dynamic features of the biological reactions are large, the motility must be studied in solution. During the last decade, small-angle X-ray scattering (SAXS) has emerged as an important method for studying large-scale dynamic processes, ranging from protein folding to virus particle polymorphism. The renaissance of this method has resulted from a variety of advances in molecular biology and X-ray instrumentation, and these have dramatically increased the information content of the derived results. Modern synchrotron X-ray sources and advanced detector systems have lead to higher-resolution data in both the spatial and time domains. Computational analyses of the data have improved dramatically, resulting, in some favourable cases, in *de novo* three-dimensional density functions from SAXS data that are comparable to a 20 Å-resolution electron-microscopy reconstruction. Model-based approaches to interpreting SAXS data have expanded their usefulness to the validation of mechanistic hypotheses involving movement or association of components independently determined at high resolution. Finally, SAXS studies have benefited from the same molecular-biology advances that provide large quantities of homogeneous material for crystallographic and NMR studies. The purpose of this chapter is to address practical aspects of SAXS as they relate to and complement macromolecular crystallography.

19.3.2. Small-angle single-crystal X-ray diffraction studies

We begin by briefly describing an obvious connection between small-angle solution X-ray scattering and single-crystal X-ray scattering, *i.e.* small-angle single-crystal diffraction (Tsuruta *et al.*, 1998; Miller *et al.*, 1999). The majority of macromolecular single-crystal studies ignore data at resolutions lower than 20 Å. Measuring these data accurately is generally difficult when collecting high-resolution data, because they are orders of magnitude stronger in intensity and frequently saturate the detector pixels or are intentionally blocked from reaching the detector by a large beam stop. It is technically challenging to record low-resolution data accurately, because they fall very close to the primary beam, where a variety of parasitic scattering effects occur. These data, however, contain information about the structure that may not be determined from only the high-resolution data. Low-resolution (∞–15 Å) data are sensitive to structures that are organized over large distances and that contribute primarily to the low-frequency terms in a Fourier series. In contrast, portions of the structure that contribute to high-frequency terms must be in precisely the same position in all the unit cells within the crystal. Two examples illustrate the importance of low-resolution terms.

Assume that an exposed loop on the surface of a protein is highly mobile. The scattering-factor curves for atoms in this loop will be highly attenuated by the large Debye–Waller factor. If the temperature factors are high enough, these atoms will contribute nothing to the high-resolution data. In contrast, these atoms will contribute strongly to the low-resolution data. If the low-resolution terms are included in the Fourier series, the atom positions will not appear as individual atoms; instead, an envelope of density describing the statistically distributed positions of these atoms will be visible, and this can aid significantly in the modelling of the loop.

A second example is the nucleic acid within a spherical virus. The nucleotides generally do not display the symmetry of the icosahedral capsid, although in some cases segments of RNA or DNA clearly interact with the protein and are therefore visible at high resolution. The RNA density is not usually visible if only higher-resolution data are used, and the virus particle appears empty. The reason for this is that the RNA is best described as a

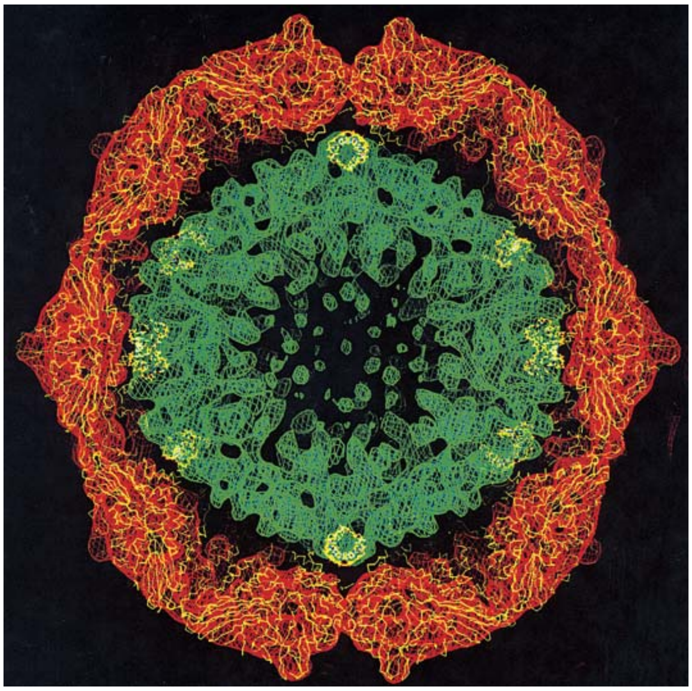

Figure 19.3.2.1
A cross section of the electron-density map of sFHV at 14 Å resolution. The density shown in red corresponds to the protein capsid, while density in green corresponds to the bulk RNA or dynamic protein segments. The Cα backbone of the atomic model of the protein capsid seen in the high-resolution structures of sFHV is shown as yellow traces, and the model of the ordered pieces of duplex RNA is shown as a stick model. The high-resolution protein model fits the electron-density map very well. The ordered RNA model is buried in the RNA density in green.

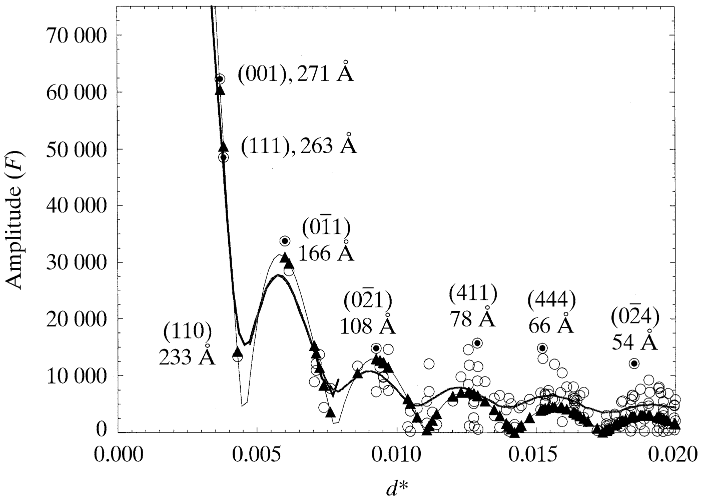

Figure 19.3.2.2

Comparison of the absolute values of single-crystal reflection amplitudes (circles), the solution scattering intensity (thick curve) and the calculated scattering intensity from a uniform sphere (thin curve).

uniform sphere within the particle, and the Fourier transform of such a sphere falls off rapidly if the sphere is relatively large. A typical RNA virus will have an internal RNA core of about 100 Å in radius. The scattering contribution of this region is virtually zero beyond 20 Å resolution. If the low-resolution data are measured accurately, the region occupied by RNA and its general level of interaction with the coat protein can be clearly seen (Fig. 19.3.2.1).

The relation between single-crystal and solution X-ray scattering is clearly illustrated in Fig. 19.3.2.2, where the scattering of a single crystal and the solution scattering of a 320 Å-diameter RNA virus are compared. The figure shows the scattering expected for a uniform sphere 160 Å in radius, the observed solution X-ray scattering from this virus and the single-crystal diffraction from the virus. All three diffraction patterns are in close agreement at resolutions below 50 Å, with the only difference being the continuous sampling of the transform in the computed and solution scattering curve and the discrete sampled transform of the crystalline virus. The RNA density in Flock house virus (FHV) shown in Fig. 19.3.2.1 illustrates the information content of the low-resolution data. DNA density functions in polyoma virus were mapped by employing similar methods (Griffith *et al.*, 1992). Low-resolution single-crystal data are also critical for applying the methods of *de novo* phase determination. Geometric solids, such as a sphere, or a low-resolution electron cryo-microscopy (cryoEM) reconstruction may serve as initial phasing models for such a strategy, and the procedure of refining and extending phases is much more robust if the low-resolution data are measured accurately (Tsuruta *et al.*, 1998).

19.3.3. Solution X-ray scattering studies

Protein crystals have high solvent content: typically 50% and as much as 80% in some cases (*e.g.* Johnson & Hollingshead, 1981; Wikoff *et al.*, 1998). Some solvent is well ordered and visible in the crystal structure. Some, referred to as bulk solvent, is dynamic, not specifically associated with parts of the repetitive lattice and can be readily exchanged within the crystal using a flow cell. The high solvent content of macromolecular crystals makes it probable that most of the features of a protein molecule that are important for its function in solution are preserved in the crystallographic structure. Cases are known, however, in which lattice forces or crystallization conditions have masked functional features of the macromolecule or induced functionally irrelevant oligomerization. A straightforward application of solution scattering is the verification of the relevance of the oligomerization state of a macromolecule observed in the crystal. The methods are complementary, because the crystal structure almost invariably leads to the correct secondary and tertiary structures for the monomer, and the SAXS experiment allows the determination of the quaternary structure of the macromolecule in solution.

The solution scattering pattern of the macromolecule can be calculated directly from a set of atomic coordinates. Scattering computed from models of different oligomerization states or from models of the monomer can be readily compared with the observed scattering pattern. In many cases, not only can the oligomer state be determined, but also the point-group symmetry of the oligomer; hence more information is available than through a solution molecular-mass determination by other physical methods. Using the same approach, effects of various ligands on the state of a protein can be studied in solution. Any large-scale structure alteration of a protein, including changes in quaternary structure or folding and unfolding, can be readily studied in solution, either as a static experiment or as a time-resolved investigation.

Recently, the search for crystallization conditions of macromolecules has been refined by the use of dynamic light scattering. Solution X-ray scattering can be even more effective because it is sensitive to molecular aggregates that are smaller than those detected by light scattering, and this broadens the radius of convergence for conditions that will produce good-quality crystals. For example, the interparticle interaction potential of proteins with a mass of less than 100 kDa can be readily measured in the SAXS experiment, and this has been shown to be an important factor in their crystallization (Bonneté *et al.*, 1997). In a particularly successful experiment, a set of small-angle solution X-ray scattering results was used to improve crystallization conditions, and this lead to single crystals that diffracted beyond 1.9 Å (Mourey *et al.*, 1997). A similar approach was used to distinguish between virus coat protein polymerization and crystallization (Petitpas *et al.*, 1998). Studies in which a number of solution conditions must be tested can be done most effectively using synchrotron small-angle scattering facilities, though it is possible to conduct such studies with a conventional X-ray source.

19.3.3.1. *Information content of solution scattering*

Solution scattering deals with samples that are randomly oriented in a solvent. Three-dimensional information is compressed to one dimension, and a one-dimensional self-correlation function (a rotationally averaged Patterson function) of the protein is obtained when the scattering function is properly Fourier transformed. Excellent books describing the information content of small-angle scattering include those by Guinier & Fournet (1955) and Glatter & Kratky (1982), and for modern perspectives see Feigin & Svergun (1987). Concise reviews with a strong focus on structural biology have also appeared, including those by Trewhella (1998) and Koch (1991). These reviews describe the theoretical background, experimental considerations and ways of extracting structural information. None of these take our perspective, which is addressed to the sceptical crystallographer.

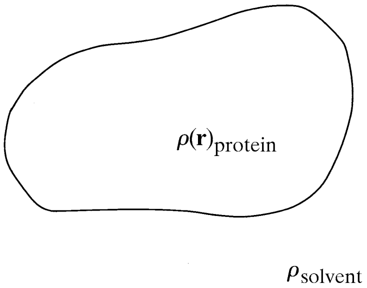

Figure 19.3.3.1
Definition of electron-density contrast. The excess electron density of protein particles over that of the solvent, $\Delta\rho(\mathbf{r}) = \rho(\mathbf{r})_{\text{protein}} - \rho_{\text{solvent}}$, is the origin of solution X-ray scattering.

Assume a monodisperse protein solution. X-ray scattering from the solution originates from the excess electron density of protein particles over that of the solvent, $\Delta\rho(\mathbf{r}) = \rho(\mathbf{r})_{\text{protein}} - \rho_{\text{solvent}}$ (Fig. 19.3.3.1). Note that $\rho(\mathbf{r})_{\text{protein}}$ is typically only about 30% higher than ρ_{solvent}, and that $\Delta\rho(\mathbf{r})$, the electron-density 'contrast', depends on the solvent composition. The scattering intensity observed for such a system is given by

$$\begin{aligned} I(Q) &= F(Q)F^*(Q) \\ &= \int\limits_{\mathbf{r}_1\mathbf{r}_2} \Delta\rho(\mathbf{r}_1)\Delta\rho(\mathbf{r}_2)\exp[-iQ(\mathbf{r}_1 - \mathbf{r}_2)]\,\mathrm{d}V_1\,\mathrm{d}V_2, \end{aligned} \quad (19.3.3.1)$$

where $Q = 4\pi\sin\theta/\lambda$ (2θ is the scattering angle and λ is the wavelength of the X-radiation used). Owing to the rotationally averaged nature of solution scattering, the exponential term may be substituted with the Debye function, $(\sin Q\mathbf{r})/Q\mathbf{r}$, giving

$$I(Q) = \int\limits_{\mathbf{r}} 4\pi\mathbf{r}^2\Delta\rho(\mathbf{r})^2(\sin Q\mathbf{r})/Q\mathbf{r}\ \mathrm{d}\mathbf{r}. \qquad (19.3.3.2)$$

Guinier & Fournet (1955) showed that equation (19.3.3.2) can be approximated by a Gaussian function at relatively small scattering angles resulting in

$$I(Q) = I(Q = 0)\exp(-Q^2R_g^2/3). \qquad (19.3.3.3)$$

This approximation is theoretically valid for $Q \leq 1/R$. Physical parameters of the system that can be determined from the solution scattering experiment are R_g, the radius of gyration of the molecule and $I(Q = 0)$, the scattering intensity at zero angle. The radius of gyration is defined as the root-mean square of the distances of all electrons from their centre of gravity. The radius of gyration can be related to characteristic dimensions of relatively simple objects. For instance, $R_g^2 = (3/5)R^2$ for a sphere of radius R, and $R_g^2 = (a^2 + b^2 + c^2)/5$ for an ellipsoid with semi-axes a, b and c (Feigin & Svergun, 1987). The scattered intensity at zero angle is proportional to the square of the molecular mass of the macromolecule at a defined number concentration. A plot of $\ln I(Q)$ *versus* Q^2 is called a Guinier plot, and if the system is monodisperse and the macromolecule is relatively globular in shape, the plot will be linear up to at least $Q_{\max} = 1/R_g$ (Fig. 19.3.3.2*a* inset). The Guinier plot should begin at a Q value significantly smaller than $1/R_g$. In practice, many investigators take the Q range for the plot to higher Q values such as $Q_{\max} = 1.5/R_g$, or nearly to $2.0/R_g$, since the Guinier plot is often linear to higher Q values. Significant deviation from linearity in the Guinier region is an indication of polydispersity or an extreme deviation from globular shape, such as a cylinder. The solution scattering intensity is proportional to the molecular mass of a particle, thus it is very sensitive to the presence of even a trace amount of large oligomers. Discrete oligomeric states can be identified by the electron pair distance correlation functions as

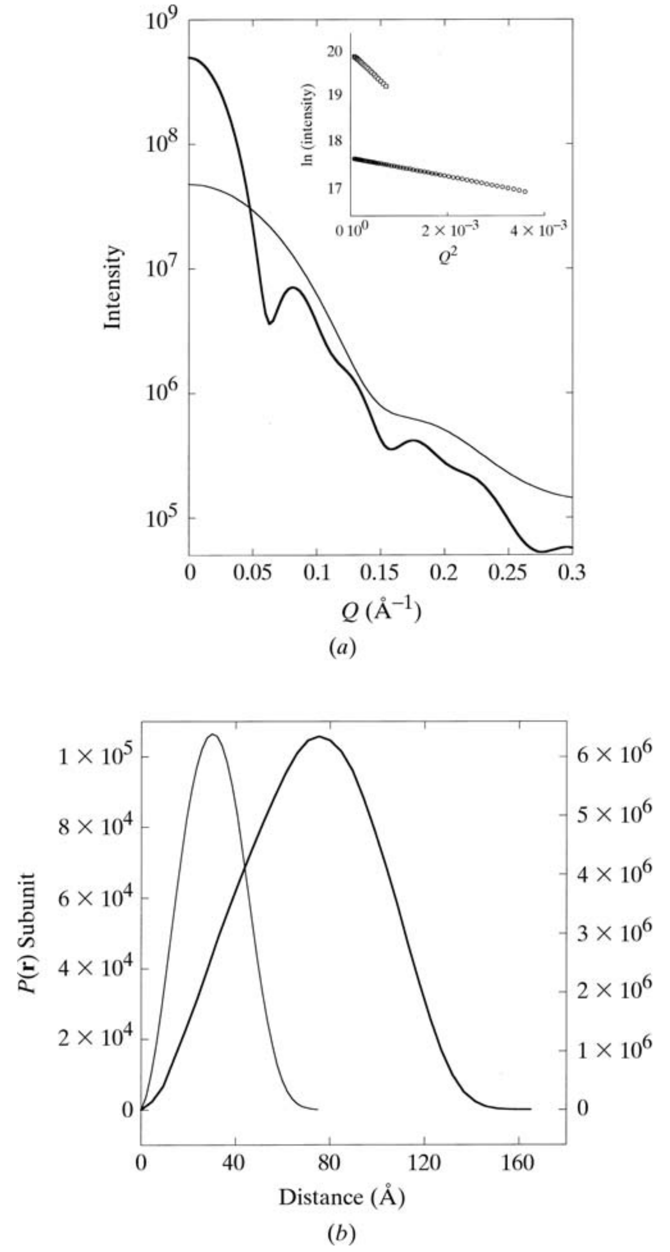

Figure 19.3.3.2
(*a*) The calculated solution X-ray scattering curves from the crystal structure of *Salmonella typhimorium* glutamine synthetase. Glutamine synthetase is composed of 12 identical 469-residue subunits and forms a functional dodecameric assembly (PDB entry 2GLS; Yamashita *et al.*, 1989). The single subunit was computationally isolated, and the solution scattering curves for the subunit (thin line) and the assembled form (thick line) were calculated with a 3 Å-thick hydration layer of 0.03 e Å^{-3} using *CRYSOL* (Svergun *et al.*, 1995). The curves are normalized to an identical weight concentration, that is, the number concentration of the dodecamer is 1/12 of that of the subunit, giving a 12-fold increase in $I(Q = 0)$. The inset shows Guinier plots of the calculated scattering curves. The radii of gyration determined by the Guinier plot to $Q \simeq 1.0/R_g$ (solid-line fit) for the subunit and the assembled form are 24.1 and 55.8 Å, respectively. The 'extended' Guinier plots to $Q \simeq 2.0/R_g$ (circles) give 23.9 and 56.5 Å. Note that both Guinier plots are quite linear beyond $Q \simeq 2.0/R_g$, although the Guinier approximation is theoretically valid to $Q \simeq 1.0/R_g$. It should be noted, however, that the 'extended' Guinier plot tends to give significantly smaller R_g for elongated shapes. (*b*) The electron distance distribution functions. The pair distribution functions $P(\mathbf{r})$ were calculated from the scattering curves in (*a*) using *GNOM* (Svergun, 1992). The maximum intramolecular distance is 75 and 160 Å for the subunit and the assembled enzyme, respectively. The $P(\mathbf{r})$ gives the radius of gyration as 23.6 Å for the subunit and 55.0 Å for the assembled enzyme.

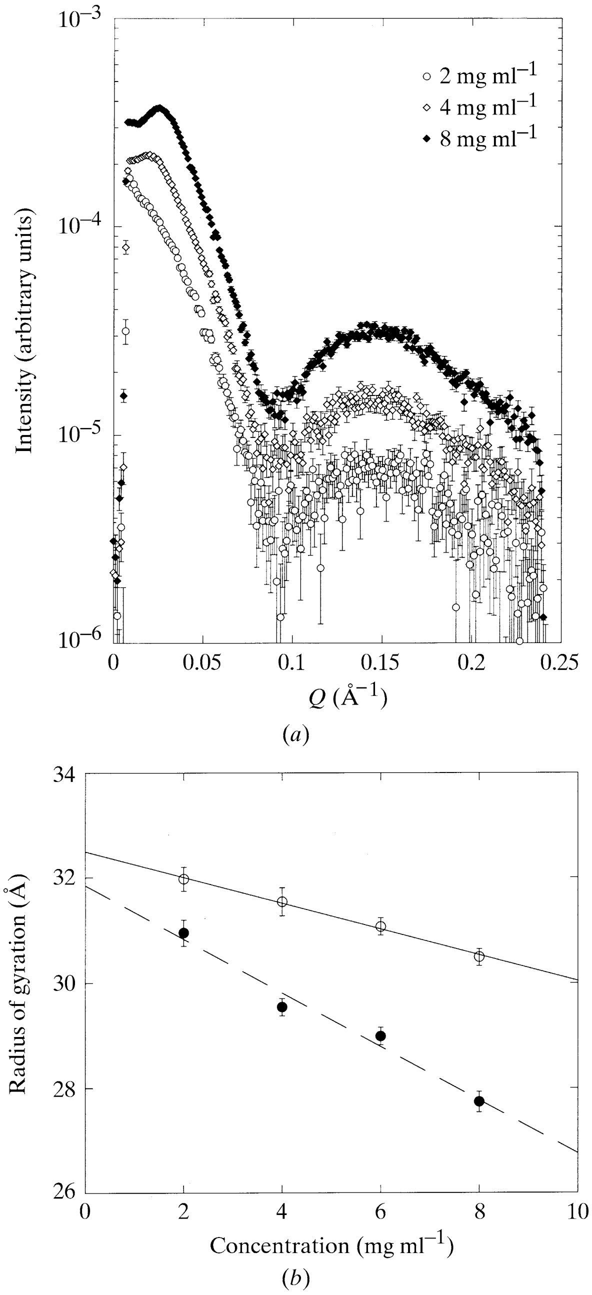

Figure 19.3.3.3
(*a*) Interparticle interference in biological small-angle scattering. Scattering from myelin P0 glycoprotein solubilized in 0.1% SDS, recorded at 2, 4 and 8 mg ml^{-1} (Inouye *et al.*, 1999). (*b*) Plots of measured radii of gyration of *E. coli* aspartate transcarbamoylase catalytic trimer *versus* concentration in the absence (open circles) and presence (filled circles) of the bisubstrate analogue *N*-phosphoneacetyl-L-aspartate (E. R. Johnson, H. Tsuruta & H. K. Schachman, unpublished data).

shown in Fig. 19.3.3.2(*b*). A second contribution to nonlinear Guinier plots is interparticle interference due to strong interactions among particles. In these cases, the particle correlation function is overlaid on the scattering function from the molecular envelope. Strong interparticle interference is illustrated in the example in Fig. 19.3.3.3. The P0 glycoprotein was solubilized with sodium dodecyl sulfate (SDS), whose net charge expels solubilized protein particles from each other, generating a correlated interparticle distance in the range of 250 Å. While the correlation is rather weak at 2 mg ml^{-1}, much stronger interference is seen at higher concentrations. This is an extreme example of interparticle interference, because a noticeable interference peak is observed in a much higher concentration range, well over 10 mg ml^{-1}, for most soluble proteins. Smaller proteins often exhibit more pronounced interparticle interference at lower concentrations than larger proteins, perhaps because the number concentration of protein molecules is higher with smaller proteins. In the case of the 100 kDa protein in Fig. 19.3.3.3(*b*), no detectable interference peak is seen. While Guinier plots are linear throughout the concentration range studied, the slope, *i.e.*, the radius of gyration, gradually decreases as the protein concentration is increased (data not shown). Also note that a small inorganic molecule could change the interparticle interference, as seen in slight change in the slope of the R_g *versus* concentration plot. This small ligand induces a conformational change in the protein, which alters its electrostatic properties. The best results are usually obtained when scattering curves are recorded at a few different protein concentrations and then extrapolated to infinite dilution. This procedure generates a scattering curve free from interparticle interference. Extrapolated values of R_g are often used to assess the magnitude of protein conformational changes. The interparticle interference, on the other hand, could be used to evaluate electrostatic properties of the protein, though this effect has not yet been clearly linked to any specific physical parameter, except the second virial constant. Note that the positive slope of the R_g *versus* concentration plot is an indication of either concentration-dependent oligomerization or non-specific aggregation. Different solution conditions should be tested to avoid a positive slope. The forward scattering intensity $I(0)$ is calculated by extrapolating the Guinier plot to $Q = 0$. $I(0)$ is proportional to the number of electrons in a particle, though it depends on the solvent electron density, given the definition of electron-density contrast. This complicates the determination of absolute molecular weight. Relating the measured $I(0)$ values to the molecular mass of the protein thus requires a well characterized monodisperse protein system with a known molecular weight for calibration. A solution of hen egg lysozyme or bovine serum albumin is often used. These proteins, however, tend to show significant changes in scattering intensity at very small angles due to radiation-induced aggregation under a full synchrotron-radiation beam. Synthetic polymers such as polyethylene are convenient standards because of their high stability; however, they scatter X-rays orders of magnitude more than many protein solutions, making it difficult to scale the data to such a standard. The problem is not usually serious, as most biological studies deal with proteins of known molecular mass. Studies of oligomeric proteins are simplified, because a species of known molecular mass, *e.g.*, a monomer, usually serves as an internal standard. The Guinier plot $\ln I(Q)$ *versus* Q^2 is no longer linear, even at small angles, when the shape of the protein deviates significantly from a globular shape. A plot of $\ln QI(Q)$ *versus* Q^2 gives a radius of gyration of the cross section and mass per unit length for a rod-like particle as well as a radius of gyration of thickness and mass per unit area (Feigin & Svergun, 1987; Glatter & Kratky, 1982).

Other information obtained directly from the experiment when there is no *a priori* knowledge of the structure is the electron pair distribution function $P(\mathbf{r})$, *i.e.*, the histogram of distances of all possible pairs of electrons within a particle (Fig. 19.3.3.4). This quantity is obtained from the Fourier transform of the observed scattering intensities. Fourier termination effects and smearing of scattering curves due to the use of a nonideal experimental geometry must be considered in the derived result. Algorithms have been developed to incorporate the experimental geometry in the back Fourier transform (Glatter, 2004; Moore, 1980). The use of nearly parallel, focused synchrotron X-ray beams, with a small beam cross section and a long sample-

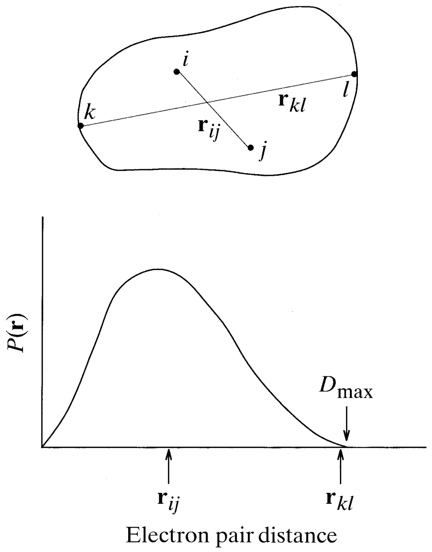

Figure 19.3.3.4
Definition of the electron pair distance distribution function $P(\mathbf{r})$. It is a histogram of all electron pair distances within a particle as depicted here. The largest dimension of the molecule $D_{\max}$ is determined from the point where $P(\mathbf{r})$ falls to zero.

to-detector distance, often eliminates the need for desmearing scattering curves and this leads to $P(\mathbf{r})$ functions with minimal errors from data correction and manipulation. $P(\mathbf{r})$, in turn, gives R_g and $I(Q = 0)$:

$$R_g = (1/2) \int^{D_{\max}} \mathbf{r}^2 P(\mathbf{r})\, \mathrm{d}\mathbf{r} \Big/ \left(\int^{D_{\max}} P(\mathbf{r})\, \mathrm{d}\mathbf{r} \right), \qquad (19.3.3.4)$$

$$I(0) = 4\pi \int^{D_{\max}} P(\mathbf{r})\, \mathrm{d}\mathbf{r}. \qquad (19.3.3.5)$$

The entire scattering curve is used to obtain $P(\mathbf{r})$, thus giving more accurate values for R_g and $I(0)$ than those from a Guinier plot, even when the data do not cover many of the scattering angles below $Q = 1/R_g$. The values of R_g obtained from $P(\mathbf{r})$ tend to be less sensitive to trace amounts of contaminating higher aggregates.

19.3.3.1.1. Solution scattering and crystal structures

SAXS is an extremely powerful method for studying the relative change in molecular weight, and thus the oligomerization state, of a protein system. Such studies are useful in the case of proteins that change in quaternary structure as a means of regulating biological function. Changes in association state such as $n\mathrm{A} \leftrightarrow \mathrm{A}_n$ lead to a large change in $I(0)$, which is proportional to the square of the molecular mass and to the number of particles in solution. In the example illustrated in Fig. 19.3.3.2, the formation of a dodecameric assembly composed of 12 identical subunits at a constant weight concentration results in the increase in $I(0)$ by a factor of 12.

The radius of gyration can be readily calculated with atomic coordinates, employing a program such as *X-PLOR*. This provides a quick means of verifying the overall crystal structure in solution. R_g values measured in solution are often larger, by up to a few ångstroms, than those calculated from atomic coordinates. Such differences are larger than statistical errors in a carefully planned set of experiments, although trace amounts of molecular aggregates due to the presence of naturally present higher oligomers, impurities or radiation-induced aggregation could increase apparent radii of gyration. The apparent protein envelope may be enlarged significantly by the presence of structured water molecules surrounding the protein. Strongly associated water molecules on the protein surface are significant, because the electron-density contrast between a protein and a solvent is small (Lattman, 1989). A recent study by Svergun, Richards *et al.* (1998), combining X-ray and neutron solution scattering techniques, verified that the hydration layer is critical when interpreting solution X-ray scattering curves based on crystal structures, because crystallographic structures underestimate the extent of the hydration layer. This layer is about 3 Å thick, with an average density about 10% higher than that of bulk solvent. The program *CRYSOL*, developed by Svergun *et al.* (1995), has incorporated the first hydration layer in the calculation of scattering curves and radii of gyration, providing estimates of the scattering close to those observed experimentally.

The Debye formula, (19.3.3.6) below, demonstrates that solution scattering intensity is sensitive to the overall shape of the molecule and can readily follow changes in particle dimensions. The intensity of scattering is given by

$$I(Q) = \sum_i \sum_j \Delta\rho(\mathbf{r}_i)\Delta\rho(\mathbf{r}_j) \sin[Q(\mathbf{r}_i - \mathbf{r}_j)]/Q(\mathbf{r}_i - \mathbf{r}_j), \quad (19.3.3.6)$$

where the indices represent individual mass elements or electrons. The solution scattering intensity from a macromolecule of known structure can be calculated readily with this expression. An entire scattering curve can be computed rapidly, even for molecules with thousands of atoms. For instance, calculation of the scattering curve of a glutamine synthetase subunit with 3636 atomic positions took approximately 30 min with a DEC Alpha workstation. The calculation of the dodecameric assembly of glutamine synthethase was performed using only α-carbon positions, instead of all atomic positions, to reduce computation time. This approach still approximates the molecular envelope of this large molecular complex very well, and the effect of the hydration layer could be incorporated, as proposed by Lattman (1989). Alternatively, three-dimensional objects can be approximated by a sum of spherical harmonics (Harrison, 1969; Stuhrmann, 1970), and the Fourier transform of the spherical harmonic expansion is an effective method for evaluating the Debye formula. The program *CRYSOL*, developed by Svergun *et al.* (1995), can compute the entire scattering curve for the dodecameric glutamine synthetase in 10 min using this method. Explicit incorporation of symmetry allows a solution scattering curve from giant molecular complexes, such as an icosahedral virus particle, to be computed efficiently (Zheng *et al.*, 1995).

19.3.3.1.2. Low-resolution model determination using solution scattering

The coordinates for a structure are often unavailable, but its general shape is known from electron microscopy or hydrodynamic studies. Pilz *et al.* (1979) demonstrated that reasonable scattering patterns from complex systems could be generated using a model that approximated the shape of a large complex with a number of uniform-density spheres. This approach has been improved over the years to make it less dependent on initial models. For instance, a genetic algorithm was recently used to select a few best models composed of uniform-density spheres to generate density functions in close agreement with solution scattering data (Chacón *et al.*, 1998). A program for this approach, *DALAI_GA*, has recently been released. There have been other effective approaches to the determination of low-resolution structures from solution scattering, including Monte Carlo methods (Olah *et al.*, 1995) to select the most plausible model among many possibilities. On the other hand, the program

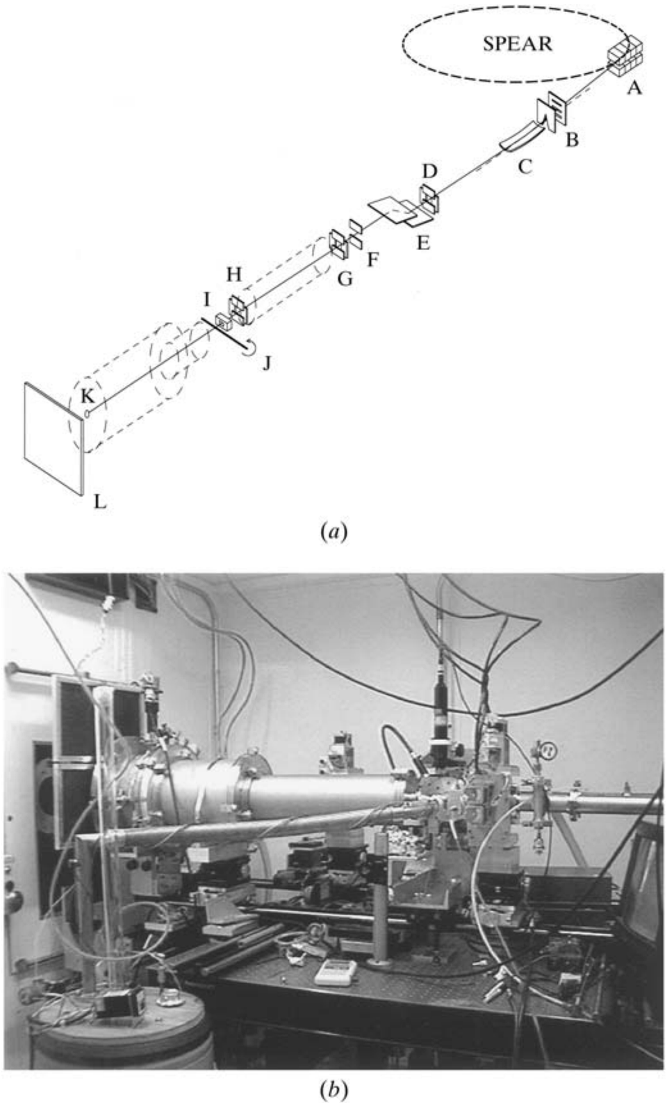

Figure 19.3.3.5
A small-angle X-ray scattering instrument on BL 4-2 at the Stanford Synchrotron Radiation Laboratory. (*a*) A diagram of the instrument composed of an eight-pole wiggler source (A), mirror slits (B), toroidal focusing mirror (C), monochromator slit (D), double-crystal monochromator (E), fast beam shutter (F), beam-defining slit (G), guard slit (H), ion chamber (I), crystal spindle axis (J), which would be replaced with a solution sample cell for solution X-ray scattering, beam stop (K) and an image plate detector (L), which would be replaced with a gas-chamber detector for solution scattering. Vacuum beam flight paths are drawn in dotted lines. (*b*) A view of the instrument as configured for small-angle single-crystal diffraction with a crystal-to-detector distance of 1.3 m. Some of the components in (*a*) are also seen in (*b*).

DAMMIN uses simulated annealing for optimization (Svergun, 1999).

Multiple-sphere modelling approaches involve many parameters, and the verification of resulting models can be difficult. This is a fundamental problem in solution scattering, because random orientation of a protein in solution limits the number of structural parameters that can be determined reliably. The scattering curve recorded in the resolution range 700 to 20 Å, a typical angular range covered in solution X-ray scattering studies of proteins, allows only a small number of parameters to be refined, typically less than 20, according to Shannon's information theorem. Density functions for oligomeric proteins displaying specific molecular symmetry can be computed directly from the solution scattering pattern with spherical harmonic expansions that reflect the symmetry (Jack & Harrison, 1975). A set of solution scattering curves from components of an icosahedral virus particle (Schmidt *et al.*, 1983) was analysed by an icosahedral harmonic expansion technique, directly generating a low-resolution structure of the virus particle that was comparable to one determined by cryo-electron microscopy and image reconstruction (Zheng *et al.*, 1995). More recently, density functions for asymmetric particles were derived *de novo* from the solution scattering patterns with a spherical harmonic expansion and no imposed symmetry (Svergun *et al.*, 1996). An interactive modelling tool has been developed that combines the spherical harmonics approach with placement of protein-subunit coordinates in real space to construct a model for a large macromolecular complex using solution scattering data (Kozin *et al.*, 1997).

19.3.3.2. *Instrumentation for small-angle X-ray scattering*

A small-angle X-ray scattering instrument typically consists of an X-ray source, a set of X-ray optics, a sample holder and a detector system (Fig. 19.3.3.5). The source can be an X-ray tube, a rotating-anode source or synchrotron radiation. The choice of optical components depends on the type of source, beam-flux requirement and angular range to be covered. The optics system includes a beam focusing device, such as a mirror, a monochromator, beam-collimation slits, vacuum paths and a beam stop. Owing to the very weak level of X-ray scattering from solutions of biological macromolecules, caution must be taken to minimize scattering from air and window materials used in the sample holder as well as to contain elements of the system under vacuum. The choice of detector depends primarily on the level of signal expected for typical samples at the detection plane. Other factors that are crucial in choosing a detector system include active area, spatial resolution and read-out speed. The level of noise generated within an entire detector system must always be constant and preferably much lower than the weakest level of signal to be measured.

19.3.3.2.1. *Instruments on conventional sources*

Kratky cameras, which are commercially available, have been used for many years in small-angle X-ray scattering studies of synthetic polymers and relatively large biological systems (Glatter & Kratky, 1982). These instruments record scattering in only one dimension, thus they are not always suitable for the study of weak X-ray scatterers, although excellent accessibility to small angles is often achieved. More recent small-angle X-ray scattering instruments have a pinhole collimation system similar to those used on synchrotron instruments described below. They allow isotropic scattering to be measured with a two-dimensional detector (Bu *et al.*, 1998). Synthetic multilayered materials, such as Mo-B_4C, formed on a figured surface serve as a monochromator element as well as a focusing device and produce an X-ray beam with very small divergence (Schuster & Göbel, 1995). Many instruments on conventional sources could benefit from this new development in X-ray optics.

19.3.3.2.2. *Synchrotron instruments*

The needs for time-resolved capability and for measuring weak X-ray scattering have lead to the development of synchrotron small-angle X-ray scattering instruments. Most of these instruments employ the pinhole camera geometry and are suitable for fibre diffraction experiments as well. [For a review, see Koch (1988).] Major synchrotron facilities that produce radiation in the hard X-ray regime have at least one small-angle X-ray scattering instrument of this type. Gas proportional counters are common with these instruments, as they allow photon counting virtually without added noise (Petrascu *et al.*, 1998). Gas proportional counters are equipped with very fast electronics modules, allowing more than 1000 time-resolved scattering patterns to be recorded successively every second (Boulin *et al.*, 1988). The disadvantage of these detectors is the count-rate limit, *i.e.*, counting efficiency drops to below 50% at about 10^5 to 10^6 counts per second. This is due to the fact that the position of photon arrival is converted to a time domain, which is then registered in a histogram memory module. The space-to-time conversion occurs first on the delay lines incorporated in the gas-chamber detector, then the time-to-space conversion is performed by time-to-digital converters. These processes take a fraction of a µs per X-ray photon using present technologies. The position of the X-ray photon cannot be recorded effectively when another photon is being processed, thus leading to the count-rate problem mentioned above. Cipriani *et al.* (1994) proposed a new delay-line technology to increase this limit by a factor of at least 10, making gas-chamber detectors useful at high count rates. Experimenters should, however, be aware of space-charge effects in gas proportional counters. Two experimental artifacts can be observed. First, intensity near the beam stop is reduced when macromolecular complexes are studied. Second, peaks with high intensity can be reduced at their maximum, giving the impression of two closely spaced weaker peaks with a trough at the location of the true peak. Arriving photons are not counted by the detector when the local count rate exceeds the recombination rate of a detector gas molecule. Modern integration detectors, such as the image plate and the charge-coupled-device (CCD)-based detectors, have virtually no count-rate limit and have been characterized for small-angle scattering. These new detectors have certain limitations, such as a relatively slow data-acquisition rate, a problem for time-resolved studies. In general, care should be taken to match the detector to the experiment.

19.3.3.3. Experimental considerations

19.3.3.3.1. Sample preparation

Sample volumes required for one measurement are between 10 to 50 µl, occasionally more, depending on the specific design of the sample cell used. The concentration required to record a scattering curve with satisfactory statistics depends primarily on the molecular weight of the protein and the beam flux. Approximately 1 mg ml^{-1} of a small protein (10–20 kDa) is the lower limit for recording a scattering pattern with satisfactory statistics when experiments are performed with a typical synchrotron instrument equipped with a gas-chamber detector. Somewhat lower concentrations of larger molecular weight proteins may be used. Higher concentrations will improve statistics significantly and reduce exposure times, but interparticle interference may result from high concentrations. Time-resolved experiments benefit dramatically from higher sample concentrations. In addition to the scattering power of the sample, the signal-to-background ratio and overall stability of an instrument (from X-ray source and optics to detector) limit the lowest concentration for a given experiment. Although higher concentrations add dramatically to the scattering and improve statistics, sample solutions must be monodisperse. Small-angle solution scattering is not well suited to the study of polydisperse systems, which give scattering of the entire molecular population weighted by the square of the mass, although a few distinct populations of substantially different sizes may be resolved with good-quality data. Chemical components that may have been carried along in a sample preparation, such as ammonium sulfate, sucrose, chloroform or caesium chloride, should be removed. The presence of such compounds may change the electron-density contrast and X-ray absorbency of the sample. In general, this can be most effectively avoided by exhaustive dialysis with the desired buffer solutions. The outer solution used for the final dialysis should be used for the blank measurements. Scattering contributions from the buffer solution, the sample cell and parasitic scattering must be subtracted from the measured scattering curve; these can be measured accurately from a well prepared blank. Extra buffer solution should be available for sample dilution. The data quality is improved and problems with radiation-sensitive samples are readily detected when protein concentrations and biological activities of samples are measured before and after the scattering experiment. Accurate protein concentration measurements permit scattering intensities from different samples to be scaled together accurately. This is particularly important in determining molecular weight.

19.3.3.3.2. Sample-handling devices

Sample holders used in solution scattering are either Lindeman glass or quartz capillaries, or machined cells equipped with flat windows (Fig. 19.3.3.6). Glass capillaries have been widely used to contain a sample solution. A beam size significantly smaller than the diameter of the capillary is required to minimize strong parasitic scattering from the round edge of the capillary. A large beam size in the horizontal direction may be used with capillaries to obtain stronger scattering intensity without adding parasitic background. Capillary cells are suitable for measuring scattering primarily in the direction perpendicular to the long axis of the cell. The advantage of the capillary cell is the small volume of sample solution required for measurements. About 4 µl of a sample solution in a 1 mm-diameter capillary provides sufficient material for the experiment. By employing a specialized holder, a capillary cell can be placed under a vacuum, minimizing air scattering (Dubuisson *et al.*, 1997). This feature is useful for solution scattering studies of small proteins. Anaerobic samples may be sealed in a capillary.

Another common sample cell holds the solution between a pair of flat windows. This cell offers two improvements over capillary cells – a larger beam cross section may be used, which increases the number of photons incident on the sample, and a two-dimensional detector can be effectively used for recording the scattering. Flat-window cells are available that require only about 10 µl of solution. Both capillary and flat-window cells require a holder with temperature regulation. The choice of window materials for the sample container is important because of the weak sample scattering. An X-ray-transparent material is required that has little intrinsic scattering within the scattering-angle range of the sample. Common window materials include synthetic mica of high purity and certain types of polypropylene and polyamide. Etched high-quality beryllium has also been used. The windows must be thin enough to transmit X-ray photons, but rigid enough to keep a constant beam-path length through sample solutions. A valuable comparison of window materials has been published recently (Henderson, 1995). A protein solution scattering pattern and a corresponding blank scattering curve should be measured in the same sample cell, unless the cells and windows are identical.

Special sample-handling devices have been built for time-resolved studies. Stopped-flow mixers for solution X-ray scattering are routinely used by a number of research groups (Kihara,

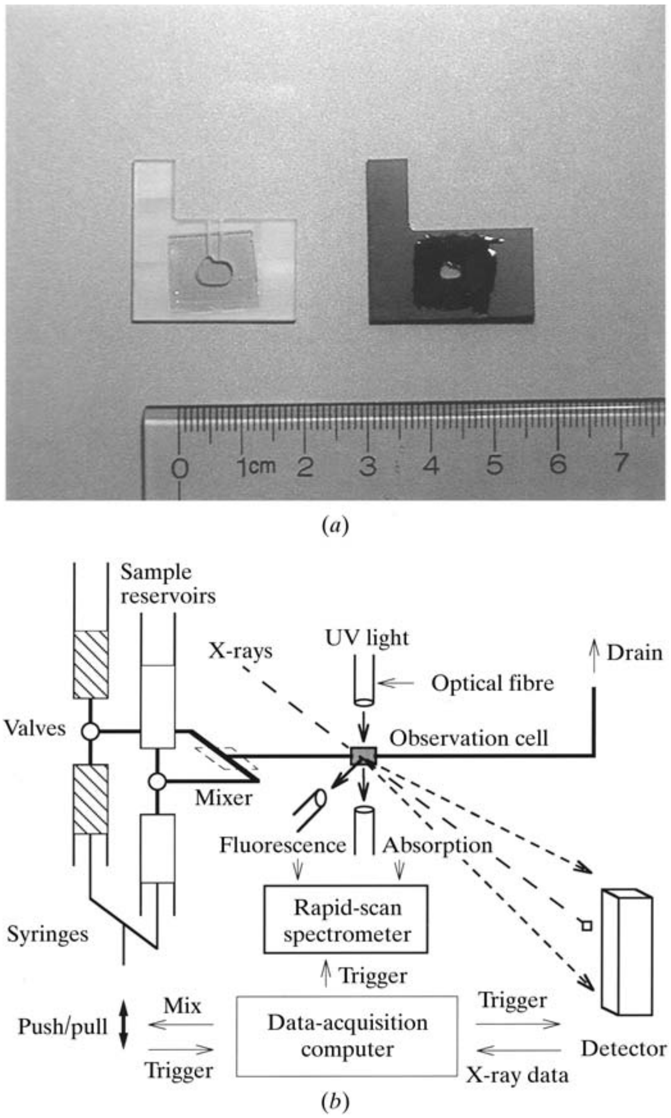

Figure 19.3.3.6

(*a*) Flat-window cells for solution scattering and (*b*) a diagram of a stopped-flow rapid mixer for time-resolved solution scattering. The solution cell to the left in (*a*) is made of polycarbonate and is equipped with two synthetic mica windows. A sample solution is injected through one of two sample loading channels using a microsyringe. The black cell to the right is made of coloured polyoxymethylene for light-activated, time-resolved studies and has a smaller sample chamber. In (*b*), two solutions, *e.g.* an enzyme solution and a substrate solution, are put in sample reservoirs, loaded into individual syringes and wait for a trigger signal from the data-acquisition system. Then the two solutions are rapidly mixed, transferred to the observation cell, typically within 5 ms or less, and a trigger signal initiates a series of time-sliced scattering-data acquisitions. This stopped-flow mixer is also equipped with optical paths to monitor absorption or fluorescence from the protein solution in the observation cell.

1994), and a high-pressure solution cell has been constructed (Czeslik *et al.*, 1996). The assembly process of tobacco mosaic virus has been studied using a temperature-jump apparatus (Hiragi *et al.*, 1988).

19.3.3.3.3. *Designing experiments*

The angular range for data collection should first be determined on the basis of the structural information required, and an instrument should be configured accordingly. Most camera systems have the flexibility to use more than one sample-to-detector distance, and they are occasionally equipped with an additional detector to cover higher angles.

The exposure time is usually determined empirically, taking into account the data statistics required, the number of conditions to be investigated and the total amount of beam time available. Typical exposure times run from a few minutes with a synchrotron source to several hours with a laboratory source. Exposure time depends strongly on the sample molecular weight, the concentration and the angular scattering range of interest. It is essential to measure the blank solvent, *i.e.*, the buffer solution in which the protein of interest is dissolved. It should be recorded with the same statistical significance as the protein solution scattering. This blank is subtracted from the observed protein solution scattering intensity, and therefore its intensity contributes to the overall counting statistics. Accurate blank measurements can take significant amounts of time and should not be ignored when planning the experiment. Blank solution scattering patterns should be recorded as often as possible. They serve as an internal control to detect systematic errors during periods of instrumental instability. In addition, the intensity of the incident X-ray beam should be integrated during the exposure time and used to scale the scattering data. Although it is useful to record the beam intensity transmitted through the solution sample, absorption is generally not a significant problem for solution scattering.

19.3.3.3.4. *Data-collection practices*

Scattering intensity measurements should be performed with a series of experiments. Solutions at different concentrations will demonstrate that the anticipated trends are observed at a qualitative level, even before the data are processed. Time-dependent aggregation or degradation are detected by recording scattering curves in a series, with a short exposure for each curve (*e.g.*, recording 10 successive scattering curves every 30 s for one protein solution). Proteins in solution may degrade in the full flux of a synchrotron-radiation beam and may exhibit radiation-induced aggregation. This is easily recognized by inspecting the very small angle region of scattering patterns that are recorded successively using short exposure times. Radiation damage can be reduced or eliminated either by attenuating the primary beam or by adding small amounts of antioxidants, which may help remove free radicals. There are several cases in which a small amount of dithiothreitol or β-mercaptoethanol prevented radiation-induced aggregation. The effects of the sulfur-reducing agents are consistent with the observation by a time-resolved single-crystal study that the sulfur atom disappears first from an electron-density map (Weik *et al.*, 2000). Temperature control is essential for most experiments. Irradiation by a 9 keV X-ray beam at a rate of 10^{11} photons s^{-1} will heat up an aqueous solution of a few µl by a fraction of a Kelvin per second if a constant-temperature device is not employed.

Preliminary data processing should take place immediately with each sample measurement. Processing 'on the fly' is particularly important when experiments are performed at a synchrotron where access may be limited. Visual inspections or statistical evaluation should be made for time-dependent aggregation at a low scattering angle. A determination of the sample molecular weight by estimating $I(0)$ and the radius of gyration from the Guinier plot would also be useful. In addition to making measurements with a blank, scattering from a standard sample should be measured, allowing the relative molecular weight of the unknown to be determined. A standard, stable, well defined known sample should be recorded prior to any other measurements. Running the same standard sample in every data-collec-

Table 19.3.3.1
List of commonly used software for solution scattering

Program	Function	Reference
OTOKO†	Data evaluation for noncrystalline diffraction	Koch (1988)
SAPOKO	Data evaluation for solution scattering	Koch & Svergun (1992)
GNOM	Indirect Fourier transform for $P(\mathbf{r})$	Svergun (1992)
IFT	Indirect Fourier transform for $P(\mathbf{r})$	Glatter (2004)
CRYSOL	Calculation of $I(Q)$ from PDB files	Svergun *et al.* (1995)
SASHA	Spherical harmonics structure determination	Svergun, Volkov *et al.* (1997)
ASSA and *ALM22INT*	Three-dimensional modelling in real space	Kozin *et al.* (1997)
DAMMIN	Simulated annealing structure determination	Svergun (1999)
DALAI_GA	Genetic algorithm structure determination	Chacón *et al.* (1998)

† An X-terminal compatible version of *OTOKO* has been developed at Daresbury Laboratory.

tion period makes it easier to compare and scale data sets recorded at different times. Sample solutions should be recovered from sample cells and stored separately, so that post-irradiation concentrations can be measured, as well as their biological activity if this can be assayed. A standard sample that gives sharp diffraction peaks of known spacing should be measured to allow the conversion of the detector channel number to Q values. A dried collagen fibre or a non-biological or more stable specimen such as cholesterol myristate is commonly used. Determining the direct beam position at the detector plane is critical in converting a detector pixel number to a Q value. The symmetric centre of a diffraction pattern of a powder or fibre sample may be used, or a thick metal foil may be inserted to attenuate the primary beam intensity and the beam position measured directly with the detector. In order to place the scattering intensity on an absolute scale, *i.e.*, to determine the scattering cross section, data from a calibrated standard sample need to be recorded.

19.3.3.3.5. *Data processing and analysis*

Processing the solution scattering data first requires scaling the raw intensity measurements to the incident or transmitted beam flux, then averaging scattering curves recorded from identical samples and subtracting measurements from the blanks described above. Corrections for detector non-uniformity or image distortion, if any, must be made, and then the detector channel numbers are converted to Q values (or inverse Bragg-scattering spacing) through the use of the scattering standard for absolute scattering-angle determination. Many facilities provide data-processing support at least to this level. Except for the image-distortion correction, commercially available analysis and visualization software can be used for this purpose. Data formats currently vary among facilities and depend on the detector systems used, but efforts are underway to establish a standard format that would enable the wide use of common data-reduction software. Common formats will make it straightforward to perform data reduction 'on the fly' and to monitor the quality of the data closely. Unfortunately, the size of the biological small-angle scattering community is not conducive to costly development of commercial software, so user friendliness has not generally been a priority in its development.

Plots of I *versus* Q that are corrected for all the known experimental factors are obtained from the data processing, and structural parameters may be derived from these data. The molecular weight and the radius of gyration can be derived immediately from the Guinier approximation. Calculation of the optimal electron pair distribution function by computing the Fourier transform of the intensity function provides the only 'real-space' data directly obtainable from the experiment. The program *GNOM* developed by D. Svergun is widely used for this purpose and may be obtained from the program author. An algorithm developed by P. Moore has been widely implemented, and software developed by Glatter *et al.* (Glatter, 2004) is available. Table 19.3.3.1 lists software suites frequently used in interpreting solution X-ray scattering data.

19.3.3.4. *Recent applications of solution X-ray scattering in structural molecular biology*

Solution X-ray scattering provides a direct means of measuring shape at low resolution, *i.e.*, the radius of gyration, the maximum dimension within a protein and the relative molecular weight. Determining the oligomeric state of a protein system is straightforward. Dimensional parameters for simple objects can be obtained indirectly by fitting the observed pattern with spherical or higher-symmetry harmonics. The concept can be extended by use of partial structural models obtained by crystallography and NMR to construct a low-resolution model of large macromolecular complexes that are not amenable to these high-resolution techniques. The refinement of such models against the solution scattering data of the putative complex bridges between atomic resolution structures and biological functions performed by large complexes. Time-resolved studies expand knowledge derived by a variety of structural techniques into the context of experimental molecular dynamics. The examples given below demonstrate some such complementing aspects of solution X-ray scattering studies.

19.3.3.4.1. *Studies of proteins in solution that complement high-resolution structures*

Recent advances in solution scattering data interpretation have made it possible to determine three-dimensional structures at resolutions comparable to those of electron microscopy. In some cases, low-resolution structures were derived from solution X-ray scattering independent of a structural model obtained by other structural techniques. Svergun *et al.* (1994) derived a 15 Å-resolution model of 50S ribosome using the spherical harmonics method. The low-resolution structures of the dimeric and tetrameric forms of pyruvate decarboxylase were obtained by the same method from X-ray solution scattering data (König *et al.*, 1992) before the crystal structure was published. The X-ray structure, at a comparable resolution, was in close agreement with the solution scattering result. The same enzyme obtained from different organisms has also been modelled with solution scattering data.

Calcium-binding proteins have been extensively studied by solution X-ray scattering. These data first demonstrated the large conformation change of calmodulin promoted by binding Ca^{2+}

(Seaton *et al.*, 1985). Comparison of the solution scattering curve calculated for the crystal structure of calmodulin with the experimental scattering curve showed that crystal-packing forces substantially altered the solution conformation of the protein (Heidorn & Trewhella, 1988). Kataoka *et al.* (1989) reported the first glimpse of the conformational change of calmodulin induced by melittin, a model peptide for target enzymes. These early studies led to a number of important solution scattering studies on the protein–protein interaction in Ca^{2+}-regulated molecular switching, including the troponin system in muscle contraction. Krueger *et al.* (1997) recently took a combined approach to X-ray and neutron small-angle scattering by using contrast variation to obtain the first structural model of calmodulin complexed with an enzymatically active truncation mutant of skeletal muscle myosin light chain kinase.

A series of structural studies on 70 kDa heat-shock cognate protein, a molecular chaperone, combined crystallography and X-ray solution scattering. It was not possible to crystallize the whole protein, but the crystal structure of the ATPase domain was solved. ATP binding induces a conformational change in the protein, resulting in the release of a bound peptide. Wilbanks *et al.* (1995) constructed a low-resolution model of the whole molecule from solution X-ray scattering data, based on the ATPase domain crystal structure. Solution X-ray scattering was recently used to screen a point-mutated version of the protein, which retains the ATP-induced conformational change, contributing to the interpretation of the role of specific residues in the molecular chaperone mechanism (Sousa & McKay, 1998).

Solution scattering complemented high-resolution NMR structural studies in the investigation of titin (connectin), a giant muscle protein (Improta *et al.*, 1998). The high-resolution structures were determined for two immunoglobulin-like fragments of the I-band region of titin. Two ellipsoids that simulate the molecular envelopes of the two fragments were then used to model solution X-ray scattering data in order to determine the relative position of the two fragments. The resulting structural model suggests that the motions around the interdomain-connecting regions are restricted and that titin behaves as a row of beads connected by rigid hinges. A similar approach was taken for EGF domains in coagulation factor X (Sunnerhagen *et al.*, 1996).

There is a long list of large proteins or protein complexes whose solution X-ray scattering studies have made important contributions in structural biology. One study demonstrated that the quaternary structure of an allosteric enzyme, *E. coli* aspartate transcarbamoylase, in the R (relaxed) state is significantly different from that observed in the R-state crystal, suggesting that a crystal lattice could deform functional quaternary structure (Svergun, Barberato *et al.*, 1997). *A. vinelandii* nitrogenase, the key enzyme in nitrogen fixation, is composed of two proteins: Fe protein and MoFe protein, which were crystallized separately. Grossman *et al.* (1997) determined a low-resolution structure of the complex of Fe and MoFe proteins stabilized by ADP–AlF^{4-}, a nucleotide triphosphate analogue, solely from solution X-ray scattering data. This was later confirmed by a crystallographic study of the same complex (Schindelin *et al.*, 1997). A more advanced approach was used to construct the three-dimensional structure of *E. coli* F_1 ATPase, which consists of four different soluble subunits in the form of $\alpha_3\beta_3\varepsilon\delta$ (Svergun, Konrad *et al.*, 1998). Two smaller subunits, ε and δ, were disordered in the crystal structure, while NMR provided solution structures for these subunits. Solution scattering was used to construct the three-dimensional structure of the F_1 ATPase structure that incorporates all the subunits. The program *CRYSOL* was used to calculate individual scattering amplitudes by approximating high-resolution structures with sums of spherical harmonics. Then individual amplitudes were combined, according to the relative positions of all subunits, while the subunits were moved with respect to each other to fit the experimental scattering amplitudes obtained for the whole complex. The programs *ASSA* and *ALM22INT* were used to construct the most plausible model for the complex. A 32 Å-resolution structure of *M. Sextra* V_1 ATPase was determined *ab initio* using the spherical harmonics method (Svergun, Aldag *et al.*, 1998). Here, a three-fold molecular symmetry in the A_3B_3 part, which resembles $\alpha_3\beta_3$ in F_1 ATPase, reduced the number of parameters. The model structure of V_1 ATPase has a 110 Å-long stalk region, corresponding to the total mass of the $CDEFG_3$ part of the complex that connects V_1 to the V_0 domain embedded in the membrane.

X-ray scattering amplitudes have recently been used in the correction of the contrast-transfer function in cryo-electron microscopy in an attempt to improve the fidelity of reconstructed electron-microscope models (Thuman-Commike *et al.*, 1999). A low-resolution structure model derived from solution X-ray scattering and electron microscopy was used to obtain initial phases for determining the crystal structure of *E. coli* ClpP, a molecular chaperone (Wang *et al.*, 1997).

19.3.3.4.2. Time-resolved studies

The advent of synchrotron-radiation sources made time-resolved X-ray studies of biological macromolecular systems possible. Time-resolved small-angle scattering studies on noncrystalline systems, such as skeletal muscle fibres and proteins in solution, are among the first studies of this type. There is still no other structural technique that offers the means of studying large, real-time conformational changes of macromolecular complexes that cannot be contained within a crystal lattice. This aspect of time-resolved solution scattering thus complements time-resolved Laue crystallography. Arguably, the most important contribution of small-angle solution scattering in recent years is the study of temporal changes in biological molecules resulting from changes in the solution environment. These changes are frequently induced by rapid mixing using a stopped-flow apparatus or a temperature jump that allows a virtually synchronous initiation of a reaction, so that the data reflect a common state for the vast majority of the molecules in solution. The changes may be associations, dissociations [*e.g.* the self-assembly of tobacco mosaic virus (Potschka *et al.*, 1988) and microtubule assembly and oscillation behaviours (Mandelkow *et al.* 1989)], as well as changes in quaternary structure. In time-resolved studies of the allosteric transition of *E. coli* aspartate transcarbamoylase (Tsuruta *et al.*, 1994), a structural intermediate during the enzyme reaction that differs from representative T and R quaternary structures was sought. As the technique has matured, a number of challenging studies have recently been conducted. Many of these time-resolved studies are focused on protein folding, as mentioned below.

19.3.3.4.3. Protein-folding studies

There have been a number of solution X-ray scattering studies on protein folding in recent years, in which proteins of low molecular weight had to be investigated under low electron-density contrast due to the presence of denaturing agents, such as urea, at high concentration. Solution X-ray scattering complements other structural techniques used in protein-folding studies, as this is the only technique available for learning how compact a protein is in solution. A Kratky plot of solution scattering data serves as a quick means of determining whether a protein is folded or unfolded. Recently, the singular value decomposition method was applied to this class of problems and revealed a folding intermediate of lysozyme (Chen *et al.*, 1996). This study has recently been expanded to a time-resolved study, which revealed a compact folding intermediate that has not yet formed a hydrophobic core (Chen *et al.*, 1998). Similar studies are being carried out on other protein systems. Arai *et al.* (1998) reported that β-lactoglobulin undergoes a similar folding pattern while it forms a folding intermediate with a hydrophobic core within 100 ms. Uversky *et al.* (1998) reported association-induced folding of globular proteins. Pollack *et al.* (1999) developed a micro-machined mixer to study folding of cytochrome *c* in the sub-millisecond regime.

Chapter 19.4. Small-angle neutron scattering

D. M. Engelman and P. B. Moore

19.4.1. Introduction

Diffuse scatter results when X-ray and neutron beams pass through gases and liquids. It is caused by local inhomogeneities, which all fluids invariably contain, at least transiently, and information about them can be obtained by analysis of the scatter they cause. This diffuse scatter is rotationally symmetric about the direction defined by the incident beam because, on average, gases and liquids are isotropic, and it does depend on scattering angle, 2θ. The intensity of the diffuse X-ray scatter of water, for example, is small at small 2θ, and it reaches a maximum at equivalent Bragg spacings equal to the reciprocal of the average oxygen–oxygen distance. In addition to a 'water ring' at high scattering angles, the diffuse scatter of macromolecular solutions includes a peak at $2\theta = 0$, due to the presence of the macromolecules themselves. If ångstrom-wavelength radiation is used, the central macromolecular peak is entirely contained in the region where $\sin(2\theta) \simeq 2\theta$. This is the region examined in small-angle scattering experiments.

Several properties of macromolecules can be determined by analysing their small-angle solution scattering, among them molecular weight, radius of gyration and maximum linear dimension. Approximate shapes can sometimes be obtained, and if a macromolecule is a complex of different chemical species, information about the distribution of its components may emerge. Hydration and conformational changes are also studied this way.

The molecular properties that can be investigated by small-angle scattering are the same for thermal neutrons and X-rays, but the advantages of neutrons are so great that if the equipment required were not so expensive, not many would do small-angle X-ray scattering (SAXS). They are all manifestations of the differences between the ways in which neutrons and X-ray photons interact with matter. For example, thermal neutrons have very low kinetic energies ($\simeq kT$), and, consequently, the energy they deposit in a sample when they are scattered inelastically is negligible. X-ray photons have large energies, and when they are absorbed or scattered inelastically, damaging amounts of energy are deposited. Thus, samples are 'safer' in neutron beams than they are in X-ray beams.

The cross section for X-ray absorption rises so fast with increasing wavelength that it is impractical to do solution-scattering experiments using X-rays with wavelengths much greater than 1.5 Å. The combination of this and the fact that X-ray beams scatter strongly off the edges of optical-track components makes it difficult to build small-angle X-ray spectrometers that measure diffuse scatter at equivalent reciprocal spacings of 0.001 Å^{-1} or less. The cross section for thermal neutron absorption is small and nearly independent of wavelength over the range 1–10 Å. Furthermore, parasitic neutron scatter is easy to control. Thus, it is comparatively straightforward to build small-angle neutron scattering (SANS) spectrometers that measure diffuse scatter at reciprocal spacings considerably less than 0.001 Å^{-1}.

Even more important to those interested in SANS are the vistas opened up by the huge difference in scattering length that exists between ^{1}H and ^{2}H (henceforth termed H and D), to which we will return below. In brief, the scatter of macromolecular solutions can be significantly altered by replacing some or all of the H atoms with D atoms. This control greatly extends the range of problems that can be addressed by SANS, and the chemical 'cost' is minimal. A perdeuterated molecule is almost identical to its protonated counterpart. The X-ray scattering of substances depends on the number of electrons they contain, and when this number is changed, chemical properties change also.

Relative to SAXS, the sole disadvantage of SANS is a phenomenon called incoherent scatter, which is a comparatively minor aspect of X-ray work. Neutrons are scattered primarily by atomic nuclei, and if a nucleus has spin, its scattering length depends on the orientation of its spin relative to that of each neutron with which it interacts. Since nuclear spins are usually unoriented in SANS samples, this spin-orientation dependence leads to a random atom-to-atom variation in scattering length. Coherent scatter, on which all diffraction effects depend, is determined by average scattering-length values. The scatter due to fluctuations about the average is incoherent, and in the low-angle region incoherent scatter manifests itself as a featureless background that is independent of scattering angle. The cross section for incoherent scattering is very large for H atoms, and since both water and biological macromolecules contain large proportions of H atoms, incoherent scatter is often a dominant source of background.

Some useful general references for small-angle scattering in general and neutron scattering in particular are Bacon (1975), Glatter & Kratky (1982) and Guinier (1955, 1962).

19.4.2. Fundamental relationships

For most purposes, a dilute macromolecular solution can be thought of as a macromolecular gas, and for that reason it is appropriate to apply Debye's theory for gas scatter to macromolecular solutions (Debye, 1915). Debye's master equation can be cast into neutron terms as follows:

$$I(Q) \propto I_0 \sum \sum b_i b_j \sin(Qr_{ij})/(Qr_{ij}), \qquad (19.4.2.1)$$

where $I(Q)$ is the amount of scattered radiation observed at Q, I_0 is the intensity of the incident beam, b_i and b_j are the scattering lengths of the ith and jth atoms in the molecule, r_{ij} is the distance between atoms i and j, and $Q = (4\pi/\lambda)\sin\theta$, λ being the wavelength of the radiation used and θ being half the scattering angle. When applied to molecules in solution, both summations must include not only all the atoms that are covalent components of the molecule in question, but also all the associated solvent atoms, because when a macromolecule dissolves, the inhomogeneity created includes the counterions associated with it, its solvation layer *etc.* Equation (19.4.2.1) holds for a single molecule; if the number of molecules contributing to scattering in some sample is N, the scattering profile measured will be N times the profile due to a single molecule. The inhomogeneities responsible for small-angle scatter have linear dimensions of the order of 10 Å or more and, hence, have volumes that contain large numbers of atoms. In addition, interatomic spacings cannot

Copyright © 2012 International Union of Crystallography

be resolved using small-angle data. Thus, it is appropriate to discuss small-angle scattering in terms of electron densities for X-rays or scattering-length densities for thermal neutrons. The scattering-length density of a volume, ρ, is given by

$$\rho \equiv \textstyle\sum b_i / V, \tag{19.4.2.2}$$

where b_i is the scattering length of the ith atom in volume V and the summation runs over all atoms in the volume.

Recasting the Debye equation in terms of scattering lengths, one obtains

$$I(Q) \propto I_0 \textstyle\int \int \rho(\mathbf{r}_i)\rho(\mathbf{r}_j)[\sin(Qr_{ij})/(Qr_{ij})] \, \mathrm{d}V_i \, \mathrm{d}V_j,$$

where $\rho(\mathbf{r}_i)$ and $\rho(\mathbf{r}_j)$ are the scattering-length densities in volume elements whose positions are described by vectors $\mathbf{r}_i$ and $\mathbf{r}_j$, $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$, and both integrals run over the volume of the entire macromolecule plus the surrounding perturbed volume. Both this equation and equation (19.4.2.1) implicitly assume that the medium surrounding each molecule is a vacuum, which is not true for the molecules in solution. The effect of solvent on low-angle scattering can be taken care of by subtracting the average scattering length of the solvent, ρ_0, from the scattering-length densities within the molecule. Thus,

$$I(Q) \propto I_0 \textstyle\int \int [\rho(\mathbf{r}_i) - \rho_0][\rho(\mathbf{r}_j) - \rho_0]_j [\sin(Qr_{ij})/(Qr_{ij})] \, \mathrm{d}V_i \, \mathrm{d}V_j. \tag{19.4.2.3}$$

The quantity $[\rho(\mathbf{r}_i) - \rho_0]$ is a *contrast*, and, as will be shown, contrast manipulation is a major component of SANS experiments.

Equation (19.4.2.3) can be evaluated a second way, because the $(\sin x)/x$ term in the integral depends only on the distances between volume elements, not on their locations in space. Thus, a function $p(r)$ can be defined as follows:

$$p(r) \equiv \textstyle\int \int [\rho(\mathbf{r}_i) - \rho_0][\rho(\mathbf{r}_i + \mathbf{r}) - \rho_0] \, \mathrm{d}V_i \, \mathrm{d}V\mathbf{r},$$

where the integral in $\mathbf{r}$ runs over all $\mathbf{r}$ such that $|\mathbf{r}| = r$, and the integral in $\mathbf{r}_i$ runs over the entire molecular volume. Written in terms of $p(r)$, equation (19.4.2.3) becomes

$$I(Q) \propto I_0 \textstyle\int p(r)[\sin(Qr)/(Qr)] \, \mathrm{d}r, \tag{19.4.2.4}$$

where the integral runs from $r = 0$ to $r_{\max}$, the maximum atom-to-atom length within the molecule.

Note that if contrast was constant within a macromolecule, $p(r)$ would be proportional to the distribution of interatomic distances in the molecule, and for that reason $p(r)$ is often called the *length distribution*. Note also that $p(r)$ is simply the molecule's Patterson function, rotationally averaged about its origin. Note, finally, that $p(r)$ is the summation of a large, but finite, number of sharp, discrete interatomic distance peaks, each with its own weight. If the individual interatomic peaks in this 'length spectrum' could be assigned, *i.e.*, if the atoms responsible for each one could be identified, it would be possible to determine the three-dimensional structure of the molecule in question, save for uncertainty about its hand.

Since solution-scattering profiles can be computed by sine transformations of length distributions, it is reasonable to hope that a transformation might exist that enables one to compute length distributions once solution-scattering profiles have been measured. There is (Debye & Bueche, 1949; Debye & Pirenne, 1938):

$$p(r) \propto r \textstyle\int QI(Q) \sin(Qr) \, \mathrm{d}r. \tag{19.4.2.5}$$

Two practical issues must be addressed when carrying out the operation implied by equation (19.4.2.5) because the integral it contains runs from $Q = 0$ to ∞. Firstly, scattering is never measured at $Q = 0$ due to interference with the direct beam. Secondly, the largest value of Q for which $I(Q)$ is measured is always less than ∞. The absence of data at very small values of Q is easily addressed, because a soundly based method exists for extrapolating the low-angle data to $Q = 0$ (see below). The lack of data at high Q is harder to cope with, but it can be dealt with approximately using Porod's Law (Porod, 1951, 1952) and the impact of its absence on molecular parameters deduced from small-angle data is easy to estimate. In any case, it is important to realize that length distributions represent the sum total of the information that can be extracted from solution-scattering experiments.

The problem of extrapolating small-angle data to $Q = 0$ was solved by Guinier (1939). He demonstrated that, at very small angles,

$$I(Q) \propto I(0) \exp[-(QR_g)^2/3], \tag{19.4.2.6}$$

where R_g is the radius of gyration, and

$$R_g \equiv (\{\textstyle\int [\rho(\mathbf{r}) - \rho_0]|\mathbf{r}|^2 \, \mathrm{d}V\}/\{\textstyle\int [\rho(\mathbf{r}) - \rho_0] \, \mathrm{d}V\})^{1/2}. \tag{19.4.2.7}$$

The origin of the vector $\mathbf{r}$ in this equation is the centre of gravity of the macromolecule's scattering-length density distribution, *i.e.*, it is the point where

$$0 = \{\textstyle\int [\rho(\mathbf{r}) - \rho_0]\mathbf{r} \, \mathrm{d}V\}/\{\textstyle\int [\rho(\mathbf{r}) - \rho_0] \, \mathrm{d}V\}.$$

It follows from equation (19.4.2.6) that if the lowest-angle data collected are plotted in the form $\ln[I(Q)]$ versus Q^2, a straight line should result, the slope of which is $(R_g^2/3)$ and the intercept of which at $Q = 0$ is $I(0)$. Note that data have to be obtained at scattering angles well inside the region where $I(Q) \sim I(0)/2$ in order for this formula to hold; if the data are thus obtained, a radius of gyration estimate will emerge. The radius of gyration of an object is the root-mean-squared distance between its centre of gravity and the elements of which it is composed.

As might be expected, $I(0)$ and R_g can also be computed from $p(r)$. Consider the magnitude of $I(Q)$ at $Q = 0$. Since the $\sin x/x$ term in equation (19.4.2.4) is 1 at $Q = 0$,

$$I(0) \propto I_0 \textstyle\int \int [\rho(\mathbf{r}_i) - \rho_0][\rho(\mathbf{r}_j) - \rho_0] \, \mathrm{d}V_i \, \mathrm{d}V_j = \textstyle\int p(r) \, \mathrm{d}r. \tag{19.4.2.8}$$

Thus, $I(0)$, the forward scatter, is proportional to the integral of the length distribution. It is easy to show that R_g equals $(M/2)^{1/2}$, where M is the second moment of $p(r)$ given by

$$M = [\textstyle\int r^2 p(r) \, \mathrm{d}r]/[\textstyle\int p(r) \, \mathrm{d}r]. \tag{19.4.2.9}$$

The average atom-to-atom distance in a molecule, $r_{\rm ave}$, is easy to compute if $p(r)$ is known from

$$r_{\rm ave} = [\textstyle\int rp(r) \, \mathrm{d}r]/[\textstyle\int p(r) \, \mathrm{d}r]. \tag{19.4.2.10}$$

The reason forward scatter, $I(0)$, is interesting is its dependence on molecular weight. As equation (19.4.2.8) suggests, the forward scatter measured for a sample is proportional to N times the square of the product of the average contrast between a molecule and its solvent and the molecular volume, where N is again the number of molecules contributing to the signal observed. Since average contrasts can be estimated from chemical compositions and partial specific volumes, $I(0)$ measurements can be used to estimate molecular weights. If the $I(0)$ values of solutions of a set of molecules of similar chemical composition are compared, it will be found that $I(0)$ divided by the weight concentration of each sample is proportional to molecular weight.

This procedure for estimating molecular weights can fail. Suppose $\int[\rho(\mathbf{r}_i) - \rho_0]\, \mathrm{d}V = 0$, *i.e.*, the scattering-length density of the solvent is the same as the average scattering-length density of the macromolecule. Then $I(0)$ will be zero, the solution-scattering profile will lack a peak at small angles and no molecular-weight estimate will result. Under these conditions, the macromolecule is said to be 'contrast matched'. It is easy to contrast-match biological macromolecules in the context of SANS experiments, because all biological macromolecules that have not been labelled with ^{2}H have average scattering-length densities between those of H_2O and D_2O (see below).

19.4.3. Contrast variation

19.4.3.1. Variation of solvent density

The principle of contrast variation was studied in early work by Bragg & Perutz (1952), who observed that the magnitudes of low-order reflections in X-ray studies of protein crystals were reduced as the salt concentration in the solvent was raised. Following their concept, the effective scattering density of a dissolved particle is

$$\rho(\mathbf{r}) = \rho(\mathbf{r})_{\text{solute}} - \rho(\mathbf{r})_{\text{solvent}} = \rho(\mathbf{r})_{\text{solute}} - \rho_{\text{solvent}},$$

where ρ_{solvent} is the average solvent scattering density. If we take a mean scattering density for the particle, a mean contrast, ρ, is defined:

$$\rho = \rho_{\text{solute}} - \rho_{\text{solvent}}. \qquad (19.4.3.1)$$

If the solute and solvent have equal densities, they are 'contrast matched', and the scattering from the particle vanishes at zero angle. The particle will nonetheless scatter radiation at larger angles as a consequence of internal density fluctuations, which can be useful in obtaining structural information. In the case of neutron scattering, the solvent density is most often varied by mixing D_2O and H_2O to obtain different percentages of D_2O. This strategy gives a range of solvent densities that includes the densities of most biological molecules. However, biological molecules contain hydrogen atoms that exchange with solvent, so deuteration of the environment alters their scattering density to some extent (see below). In general, all hydrogen atoms not bonded to carbon are potentially exchangeable, but not all of these will actually exchange in a typical experiment.

To describe the variation of the radius of gyration with contrast, Stuhrmann derived the useful relationship (Stuhrmann, 1976; Stuhrmann *et al.*, 1976)

$$R_g^2 = R_c^2 + \alpha/\rho + \beta/\rho^2, \qquad (19.4.3.2)$$

which separates the contributions of the internal structure of the particle (ρ_I) to its radius of gyration from the contributions of the shape (ρ_c). Scattering from the internal structure is independent of contrast; scattering from the shape is contrast dependent. The shape function is defined as having a value of one inside the particle and zero outside. The total scattering density is then

$$\rho(\mathbf{r}) = \rho\rho_c(\mathbf{r}) + \rho_I(\mathbf{r}). \qquad (19.4.3.3)$$

The contrast-independent terms in the Stuhrmann equation are

$$\alpha = (1/V_c) \textstyle\int \rho_I(\mathbf{r}) r^2 \, \mathrm{d}^3 r, \qquad (19.4.3.4)$$

$$\beta = (1/V_c^2) \textstyle\int\int \rho_I(\mathbf{r})\rho_I(\mathbf{r}')\mathbf{r}\mathbf{r}' \, \mathrm{d}^3 r \, \mathrm{d}^3 r' \text{ and} \qquad (19.4.3.5)$$

$$R_c^2 = (1/V_c) \textstyle\int \rho_c(\mathbf{r}) r^2 \, \mathrm{d}^3 r, \qquad (19.4.3.6)$$

where R_c is the radius of gyration of the shape function and V_c is its volume. The sign and magnitude of α give information on the radial density distribution of scattering density in the particle: if the outer region is higher in density than the inner region, α is positive (as, for example, in lipoproteins); if the inner region is denser, α is negative. The β coefficient represents the displacement of the centre of mass as a function of the contrast and is always positive; in real cases, β is often negligible. The Stuhrmann equation leads to a useful way to represent graphically the radius of gyration data obtained from a series of contrasts: the observed R_g^2 is plotted *versus* $1/\rho$. If β is negligible, the plot is a straight line of slope α, intercepting the $1/\rho$ axis at R_c^2. Thus, R_c is obtained by extrapolation to a point where $\rho = \infty$, and so is often termed the radius of gyration at infinite contrast. This quantity is a representation of the shape of the particle as if it had uniform internal scattering density. In a particle with two discrete regions of density, the radius of gyration for each region can be obtained from such a graph by evaluating R_g^2 where ρ is equal to the density of one region, so that R_g^2 of the non-contrast-matched region is determined. Such measurements can also be made by adjusting the solvent to match the scattering of one region to reveal the scattering of the other.

A parameter that is often useful is the contrast-match point for the particle, which reflects its overall composition including exchange.

$$\rho_M = \textstyle\sum b_I/V + nd(b_{\mathrm{D}} - b_{\mathrm{H}})/V, \qquad (19.4.3.7)$$

where ρ_M, the match point, is the solvent scattering length density at which the contrast is zero and n is the number of exchanged hydrogens multiplied by d, the fractional deuteration of the water at the match point. Typically, the match point is obtained by measuring small-angle scattering at a series of D_2O:H_2O ratios, plotting each using a Guinier plot $\{\ln[I(Q) - I(0)]$ *versus* $Q^2\}$ to obtain a value for $I(0)$ by extrapolation, and then plotting $[I(0)/C]^{1/2}$ *versus* ρ_{solvent}, where C is the particle concentration. It is often convenient to represent ρ_{solvent} as per cent D_2O. The plot should be a straight line, passing through zero at the contrast-match point. As noted above, the vast majority of biological molecules have contrast-match points at densities between those of H_2O and D_2O. If the particles are compositionally heterogeneous, the observed plot will be a weighted sum of the curves for each of the compositions present and will deviate from a straight line at low contrasts. Thus, the contrast-matching experiment can provide information on both composition and homogeneity.

While contrast variation is most often based on variation of the deuteration level in water, it is also possible to create variation by adding molecules to the solvent. As an example, a study of hydration layers was conducted by adding solute molecules, such as glycerol, at high concentration; the solute molecules alter the solvent scattering length density but do not penetrate the hydration layer (Lehmann & Zaccai, 1984).

19.4.3.2. Variation of internal contrast

A second form of contrast variation can be achieved by replacing the hydrogen atoms in biological molecules with deuterium. If, in addition, it is possible to deuterate selected regions of a particle, internal contrasts can be modified to gain information about substructures. In some cases, the opportunity arises because significant biochemical differences are present, as between the RNA and protein portions of a ribosome, the DNA and protein of a nucleosome, or the lipid and protein of a lipoprotein particle. While the intrinsic contrast may be sufficient to provide key information [as, for example, the early finding that

DNA is on the outside of nucleosomes (Bradbury *et al.*, 1976; Uberbacher *et al.*, 1982)], it can be accentuated by incorporation of deuterated biochemical precursors or reconstitution from separately labelled components.

Internal contrast can be created in single molecules by differential incorporation of biosynthetic precursors or by chemical synthesis. Differential incorporation was first used to test models of bacteriorhodopsin, using the incorporation of deuterated amino acids supplied to a culture of halophilic archae (Engelman & Zaccai, 1980), and internal labelling was used to document conformations of cholesteryl esters that had been chemically labelled in key positions (see below). Reconstitution from purified components has been used to place deuterated proteins in ribosomes and in other complexes, again with the aim of creating internal contrast to enhance the information obtained in a neutron experiment.

In general, the creation of internal contrast can be viewed as a strategy for enriching the low information content of a solution-scattering experiment by building additional information into the sample. By design, it is known what has been labelled, so the scattering given by contrasting elements provides information about the relationships of the labelled parts to each other or to the particle as a whole. A particularly informative (but difficult) strategy is to use internal contrast to measure distances between locations in a molecule or complex. Such measurements are discussed below.

19.4.3.3. Relationship of contrasting regions

Where a particle has two regions of different scattering density, the square of the total observed radius of gyration, R_T^2, can be obtained as the weighted sum of squares of the two individual radii, R_1^2 and R_2^2, and the square of the distance between the centres of scattering mass of the two regions, d_{12}^2, as

$$R_T^2 = f_1 R_1^2 + f_2 R_2^2 + f_1 f_2 d_{12}^2, \qquad (19.4.3.8)$$

where the f's are the fractions of the total scattering from each of the two regions at the solvent contrast being used in the experiment (Moore *et al.*, 1974). By varying the contrast, a set of differently weighted equations can be obtained, from which the individual radii and the separation can be derived. This method is an alternative to the Stuhrmann analysis described above. An example of the use of this approach, based formally on the parallel axis theorem of mechanics, is found in studies of the ribosome (Moore *et al.*, 1974). An alternative that has proved useful is to combine neutron and X-ray scattering data, since the weighting factors will differ for distinct regions, such as the RNA and protein components of the ribosome (Serdyuk *et al.*, 1979).

19.4.3.4. The triple isotopic substitution method

An innovation in the study of subunits in a reconstituted complex was introduced by Serdyuk *et al.* (1994), who devised a difference method to isolate the scattering from a single subunit. The method requires three particles with different deuteration levels in the subunit: one in which the subunit is heavily deuterated (contrast with the complex = ρ), one in which the subunit is not deuterated (0), and one in which the subunit is deuterated at an intermediate level ($\rho/2$):

$$I_1(Q) = |C|^2,$$
$$I_2(Q) = |C|^2 + 2(\rho/2)F[CS] + (\rho^2/4)|S|^2 \text{ and}$$
$$I_3(Q) = |C|^2 + 2\rho F[CS] + \rho^2|S|^2,$$

where C is the scattering amplitude of the complex, S is the amplitude of the subunit, and $F[CS]$ is the Fourier transform of the correlation function between the complex and the subunit. Scattering is measured (*a*) from an equimolar mixture of complexes with heavily deuterated and non-deuterated subunits and (*b*) from a sample of complexes with subunits with the intermediate level of deuteration. Subtraction of (*b*) from (*a*), weighted so that the two curves are equimolar, gives a net curve for the subunit alone (at half the scattering power that would be seen for a solution of the isolated subunits at the same concentration):

$$I_1(Q) + I_3(Q) - 2I_2(Q) = (\rho^2/2)|S|^2. \qquad (19.4.3.9)$$

The difference curve is not influenced by solvent composition, underlying order, concentration or interparticle interference effects. Thus, at the cost of some difficult biochemistry, the small-angle scattering of a subunit belonging to a large assembly can be observed *in situ*. In practice, the mixture is not equimolar, but is adjusted depending on the intermediate level of deuteration, relaxing some of the difficulty of the biochemistry.

19.4.3.5. Nuclear spin contrast variation

When atomic nuclei of nonzero spin are placed in a magnetic field, the spins orient. If the temperature is near absolute zero, the orientation results in a polarization that is seen by polarized neutrons, resulting in polarization-dependent scattering. Since polarized neutron sources are available, and since biological materials are rich in hydrogen, Stuhrmann has proposed and tested a measurement based on the following idea (Stuhrmann & Nierhaus, 1996). Consider a complex in which all of the hydrogen has been replaced by deuterium except in one subunit or ligand, and prepare a sample that can be frozen to $T < 0.5$ K, placed in a 2.5 T magnetic field and subjected to dynamic spin polarization. Scattering of polarized neutrons is measured twice, once with the hydrogen spins oriented, and once with the spins selectively depolarized using NMR saturation. The difference contains contributions from the hydrogenated region and a cross term between the region and the rest of the complex. Using a modelling approach, Stuhrmann and his colleagues have deduced a structure that locates transfer RNA molecules on a ribosome from polarized neutron data, revealing the promise of this approach (Stuhrmann & Nierhaus, 1996).

19.4.3.6. Interpretation of small-angle scattering using models

There have been many attempts to extract more information from solution-scattering experiments than the radius of gyration and forward scattering, including the distance-measuring strategies discussed below. These attempts are of two kinds: testing models and creating models. Each of these must be cast in the context of the intrinsic information content of a scattering measurement, which can be expressed in terms of the number of independent parameters, n, that can be uniquely extracted from a data set (Moore, 1980).

$$n = Q_{\max} d_{\max}/\pi, \qquad (19.4.3.10)$$

where $Q_{\max}$ is the largest Q at which statistically significant data are measured and $d_{\max}$ is the largest dimension of the particle. A further requirement, normally met in small-angle scattering, is that $Q_{\min} d_{\max}/\pi < 1$.

The information content is a subtle factor in the first class of modelling, where models are tested for agreement with scattering data. Excellent programs have been written for generating predicted scattering curves from atomic coordinates and have been used to explore perturbations between crystal structures and solution organization. A fine example is the work on ATCase by Svergun, Barberato *et al.* (1997); the article also contains references to the programs used.

A more challenging task is to work in the other direction, extracting structural information directly from a scattering curve. Considerable effort has been devoted to work in this area, using approaches based on spherical harmonics, sometimes using sets of spheres to represent structure, and occasionally integrating information from electron microscopy (Svergun, 1994; Svergun, Burkhardt *et al.*, 1997).

19.4.3.7. Use of forward scattering to measure molecular weights

The value of the scattering function at zero scattering angle, which is obtained by extrapolation using a Guinier plot, is related to the molecular weight of the particle. In the neutron small-angle scattering case, the incoherent scattering background from hydrogen provides an internal standard. Using the incoherent background as an absolute calibration of the beam intensity, and knowing the concentration and composition of particles, one can obtain good values for the molecular weight, as pointed out by Jacrot & Zaccai (1981) and Zaccai & Jacrot (1983). This approach applies particularly well to proteins, where the average scattering density does not vary much from case to case, and can provide important data on the stoichiometry of oligomeric complexes. The limit in the accuracy of the measurement arises from limitations in knowing the protein concentration.

19.4.4. Distance measurements

19.4.4.1. Theory and background

By measuring distances between chemically specified points in a macromolecule or macromolecular complex, useful information may be obtained concerning its structure. In the case of a complex with many subunits, successive inter-subunit distance measurements can be combined by triangulation to generate a three-dimensional map specifying the relative positions of subunits and, perhaps, their individual radii of gyration. The only uncertainty is the handedness if more than three distances are combined. A number of approaches exist for making distance measurements, including NMR, fluorescence and electron-microscope techniques in which labelling is employed. Neutron scattering provides a particularly simple approach to such measurements in a conceptual sense. If we consider two labelled centres in a large macromolecule or complex, the interference of the scattering from the two labelled positions, $I_x(Q)$, can be separated from the scattering of the rest of the complex by measuring the scattering of the unlabelled complex, $I(Q)$, the two singly labelled complexes, $I_1(Q)$ and $I_2(Q)$, and the doubly labelled complex, $I_{12}(Q)$, as they are related by

$$I_x(Q) = [I_{12}(Q) + I(Q)] - [I_1(Q) + I_2(Q)]. \tag{19.4.4.1}$$

Using the Debye relationship, it can be shown that the cross term will have the approximate form

$$I_x(Q) = 2f_1 f_2 \sin(d_{12}Q)/d_{12}Q, \tag{19.4.4.2}$$

where the interference intensity results from the correlation between radiation scattered from sites 1 and 2, with scattering strengths f_1 and f_2. It is a damped sinusoidal fringe with a periodicity reciprocally related to the separation between the scattering regions. If the scattering regions are very small compared with the object, there will be nodes at equal intervals in Q; if they are not, $I_x(Q)$ will be a sum of all cross correlations of label positions in the two regions.

19.4.4.2. Neutron distance measurements

In the neutron case, the usual application involves deuterium labelling of positions in the two regions, and the cross term becomes

$$I_x(Q) = 2(b_D - b_H)^2 \sum_i \sum_j (\sin d_{ij}Q)/d_{ij}Q, \tag{19.4.4.3}$$

where the first sum runs over all labelled positions in region 1 and the second over all labelled positions in region 2.

The interference experiment as a technique for studying macromolecules in solution was first proposed in 1947 as an X-ray scattering measurement in which the labels are heavy atoms (Kratky & Worthmann, 1947). It has been discussed several times since and tested (Hoppe, 1972; Vainshtein *et al.*, 1970); however, no biological application has ever been published, since the signals are small (Hoppe, 1972). In 1972, the interference idea was discovered again, but in the context of neutron scattering (Engelman & Moore, 1972). Initially, it was thought that the distance measurement would follow from inspection of the damped sinusoidal term, but it soon became evident that the size and shape of the labelled regions would have an important influence. Using a power series expansion like that originally employed by Guinier, the previous expression becomes (for small Q)

$$I_x(Q) \propto [1 - (1/6)(R_i^2 + R_j^2 + d_{ij}^2)Q^2],$$

where R_i and R_j are the radii of gyration of the subunits *in situ*, and d_{ij} is the separation of their centres of mass. It follows that (Moore *et al.*, 1978; Stöckel *et al.*, 1979)

$$R_g^2 = (1/2)(R_i^2 + R_j^2 + d_{ij}^2). \tag{19.4.4.4}$$

The second moment of a length distribution, M_{ij}, can be related to a radius of gyration. If $p_{ij}(r)$ is the length distribution of the cross term $I_x(Q)$, then

$$M_{ij} = \int r^2 p_{ij}(r)\,\mathrm{d}r = 2R_g^2.$$

Hence (Moore *et al.*, 1978)

$$M_{ij} = R_i^2 + R_j^2 + d_{ij}^2. \tag{19.4.4.5}$$

Thus, M_{ij} is the parameter that contains the information in the difference experiment. If the radii of gyration of the labelled regions are small, then the distance is well measured in a single experiment. This would be the case, for example, if the labels were single heavy atoms in an X-ray experiment. However, in most complexes of macromolecules there will be many pairwise protein–protein relationships where the radii and the separation of centres have comparable magnitudes. One approach to extracting distance information is to know the radii of the subunits *in situ*, by estimation from their molecular weights, by measurement of the isolated subunits or from triple isotopic substitution (see above). The first approach is the least desirable but the easiest, and the last approach is correct but laborious.

If a complex has eight or more distinct subunits, the number of possible measurements of M_{ij}, $n(n-1)/2$, is sufficient to solve for the distances and radii, enriching the information obtained from the experiment. The minimum number of measurements required is $4n - 6$, and for large complexes, such as the ribosome, a great excess of possible measurements exists, permitting refinement of the information through redundancy. Moore &

Weinstein (1979) have described analytical methods for solving the problem with correct error propagation.

19.4.4.3. *The statistical labelling method*

In many biological assemblies, multiple copies of a given subunit are found. In such cases, statistical labelling methods provide useful information. The basic concept is to produce two samples in which labelled subunits are randomly mixed with unlabelled subunits within the particles, and in which the ratios of labelled to unlabelled subunits is different. The difference in the scattering from the two samples will then contain shape and orientation information for the subunits (Fujiwara & Mendelson, 1996). A simple case is that of a dimer in a larger complex. Random introduction of equimolar labelled (D) and unlabelled (H) subunits will result in a mixture of complexes, where HH:HD:DH:DD = 1:1:1:1. A sample can be prepared with an equimolar mixture of all H and all D so that HH:DD = 1:1. The difference in scattering between these samples will be simply the interference cross term for the dimer, but at half the weight it would have in the case where the subunits were distinctly labelled.

19.4.5. Practical considerations

19.4.5.1. *Feasibility*

For a biological scientist, the first question is whether knowledge of the parameters that can be obtained from neutron scattering is of interest for the biological problem under consideration. If the answer is affirmative, the best course of action is to make contact with individuals who have conducted experiments in the past, as well as with biologists at a neutron-scattering facility. As a preliminary guide, a few general points are pertinent.

For a solution-scattering experiment on an unlabelled sample, typical sample volumes are 0.1–0.2 ml at concentrations of around 10 mg ml^{-1}. For contrast variation, samples dialysed to different D_2O levels will be required, so significant amounts of material need to be at hand. Making a set of measurements will require a few hours at a modern facility.

Longer collection times and significantly greater biochemical efforts will be involved for measurements with labelled material, especially if reconstitution is part of the strategy. Labelled biomolecules are most often produced by growth of organisms in D_2O (Moore & Engelman, 1976; Vanatalu *et al.*, 1993), but strategies using chemical synthesis or providing labelled precursors have also been employed. Preparation of samples with labelled ligands is usually more straightforward than the generation of reconstituted complexes, but still requires tests of homogeneity.

19.4.5.2. *Homogeneity and stability*

For measurements to be made, the samples must be transported to a neutron facility and measured for many hours. This requires stability in the usual biochemical sense, and proper experiments will include assays performed after the measurements. Damage from the neutrons themselves is minimal, but handling and transportation impose greater challenges.

Where mixed samples are employed, stability also involves resistance to exchange of subunits or ligands between complexes in the mixture. This is hard to assess in advance, the first sign of trouble often being an absence of an expected difference signal. Given shipment and measuring times, even a slow exchange is significant. With a consequent qualification of the results, cross-linking may be used to stabilize the complex.

In all scattering measurements, homogeneity of the sample is a great advantage in interpretation. However, some variation is tolerable for many purposes, and the level of purity typically sought for crystallization experiments is not usually required.

19.4.5.3. *Solvent conditions*

Background arises from the incoherent scattering of hydrogen. Consequently, the use of high levels of D_2O in the buffer improves the background, but may not be innocuous, since high levels of D_2O have been seen to induce aggregation. In cases where complexes with labelled subunits are measured, it is advantageous to suppress small-angle background scatter by contrast matching the unlabelled regions *via* solvent adjustment.

19.4.6. Examples

19.4.6.1. *Contrast variation*

An early result that changed ideas about nucleosome organization came from measurements relying on the difference in protein and DNA densities (Baldwin *et al.*, 1975; Bradbury *et al.*, 1976). Information on the organization of serum lipoproteins was also based on intrinsic scattering differences (Stuhrmann *et al.*, 1975; Atkinson & Shipley, 1984). The contrast between RNA and protein was used in early ribosome measurements (Crichton *et al.*, 1977; Moore *et al.*, 1974). Recent examples include detergent binding to membrane proteins (Timmins *et al.*, 1991) and the study of membrane protein–lipid complexes (Jeanteur *et al.*, 1994). Elegant use of contrast variation resulted in a structural explanation of the anti-cooperative binding of tRNA to synthetase, which had resisted study by other methods (Dessen *et al.*, 1978).

19.4.6.2. *Contrast matching*

In some applications, use has been made of contrast matching a large part of a complex to study a component with a contrasting scattering density. Examples include studies of ribosomal proteins *in situ* (Nierhaus *et al.*, 1983; Nowotny *et al.*, 1994), proteins of the DNA-dependant RNA polymerase (Stöckel *et al.*, 1980*a*), studies of muscle proteins (Stone *et al.*, 1998) and a view of a membrane protein in a lipid bilayer (Hunt *et al.*, 1997).

19.4.6.3. *Spin contrast variation*

Some applications of the spin contrast variation method have appeared (Junemann *et al.*, 1998; Nierhaus *et al.*, 1998).

19.4.6.4. *Specific deuteration, combination with X-ray measurements*

Many recent measurements use specific labelling and combine information with data from small-angle X-ray scattering. Studies of ligand binding (Bilgin *et al.*, 1998), hydration layers (Svergun *et al.*, 1998), troponin complexes (Olah *et al.*, 1994) and ribosomes (Svergun *et al.*, 1996) are examples that illustrate the approaches.

19.4.6.5. *Distance measurements and triangulation*

By measuring distances and radii of gyration, models of some large complexes have been created. These include a model of the relative positions of all 21 proteins in the small ribosomal subunit from *E. coli* (Capel *et al.*, 1987), a model of seven proteins from the large subunit (May *et al.*, 1992) and a model of the DNA-dependant RNA polymerase (Stöckel *et al.*, 1980*b*). Intramolecular conformational states of cholesterol esters have been observed using distance measurements on molecules chemically labelled in different regions (Burks & Engelman, 1981).

Chapter 19.5. Fibre diffraction

R. Chandrasekaran and G. Stubbs

19.5.1. Introduction

Many biopolymers are long helical structures and have a natural tendency to form fibres. This tendency severely impedes the growth of single crystals from these polymers, and even if crystals can be grown, the molecular interactions in the crystals rarely correspond to the biologically significant interactions in the fibres. Conventional macromolecular crystallography is therefore often not applicable to these systems. Fibre diffraction, however, is a powerful technique for determining the structural details of such polymers. It has been used to study a wide variety of biopolymers, ranging from simple polypeptides, polynucleotides and polysaccharides to complex filamentous viruses and cytoskeletal filaments.

Fibres can have relatively high degrees of order, although falling short of true three-dimensional crystallinity. The key difference between fibres and crystals, however, is that in fibres the fundamental structural aggregates, although parallel to each other, are randomly oriented about the fibre axis. Consequently, the diffraction pattern is cylindrically averaged. This cylindrical averaging is the defining characteristic of fibre diffraction.

On the basis of this definition, fibre diffraction may also be considered to include diffraction from many biological membrane specimens, and much of fibre-diffraction theory also applies to membrane diffraction. In general, however, the diffracting units in fibres have helical symmetry, whereas those of membranes do not.

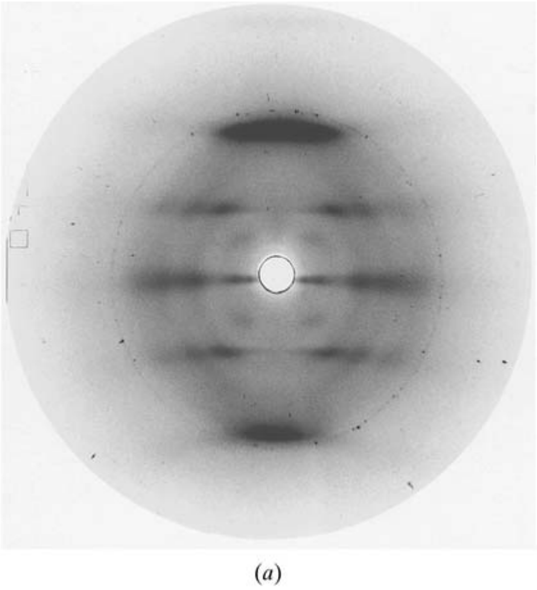
In addition to the loss of information due to cylindrical averaging, fibre-diffraction patterns reflect a generally limited degree of order and rarely extend beyond 3 Å resolution. Consequently, the number of data obtainable from a fibre is considerably less than that from a single crystal having a similar size of asymmetric unit. The use of stereochemical information to supplement the diffraction data is therefore essential. For polymers with small asymmetric units, such as polynucleotides, structural chemical information can be used to construct models consistent with the helical parameters and molecular dimensions obtained from the diffraction data. For the larger asymmetric units found in aggregates, such as viruses, initial models must be constructed in other ways. However, in all cases the combination of diffraction data and stereochemistry can be used to refine both molecular structures and packing parameters. Refinement in this way is very similar to that used in macromolecular crystallography, but because of the limited number of experimental data, stereochemical restraints are particularly important in fibre diffraction. As in crystallography, difference-electron-density maps are used in conjunction with refinement to identify missing portions and determine the correctness of the models and, in favourable cases, to locate ions and solvent molecules associated with the polymers.

19.5.2. Types of fibres

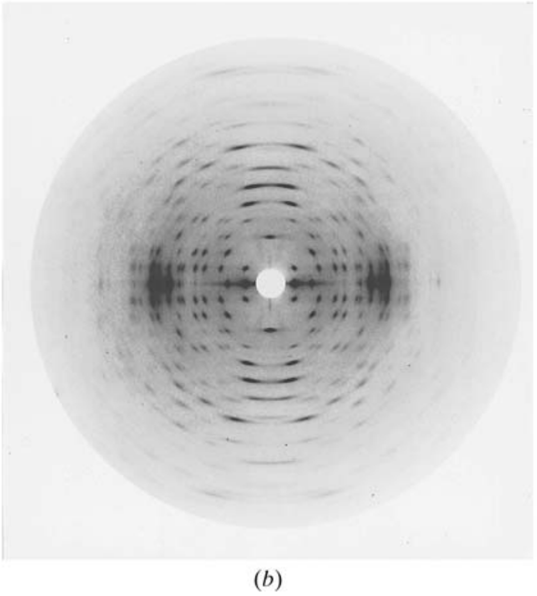
Fibres fall into essentially two classes with respect to the degree of ordering of the polymer chains. Within each class, there are varying degrees of disorder; furthermore, many fibres exhibit properties intermediate between those of the two ideal classes.

In noncrystalline fibres, the polymers are parallel to each other, but their positions and orientations are otherwise uncorrelated. Diffraction patterns from these fibres are confined to layer lines (Fig. 19.5.2.1*a*) because of the repeating nature of the polymer helix, but are otherwise continuous and correspond to the cylindrical average of the Fourier transform of a single particle.

In polycrystalline fibres, the polymers form fully ordered microcrystallites, and each fibre consists of many such microcrystallites, randomly oriented about the fibre axis. In diffraction patterns from polycrystalline fibres, the layer lines are sampled to form discrete reflections (Fig. 19.5.2.1*b*); the diffraction pattern is



(*a*)



(*b*)

Figure 19.5.2.1
X-ray diffraction patterns showing (*a*) continuous intensity on layer lines from an oriented nucleic acid fibre and (*b*) Bragg reflections from an oriented and polycrystalline polysaccharide fibre.

Copyright © 2012 International Union of Crystallography

the cylindrical average of a single-crystal diffraction pattern and is, in fact, equivalent to the diffraction pattern that would be obtained from a rotating single crystal.

Polycrystalline fibres may be disordered in various ways. For example, the helical polymers may be subject to rotational or translational disorder, and this disorder may be partial (a small number of alternative packings for each particle) or complete (for example, completely random rotational particle orientations). Rotational disorder may be coupled to translational disorder (screw disorder). The resulting diffraction patterns may contain both discrete reflections and continuous diffraction along layer lines; depending upon the type of disorder, the discrete reflections may be confined to the equator (layer line zero) or the low-resolution part of the pattern, or they may be dispersed throughout the pattern. Variations in diffraction effects due to different types of disorder have been discussed by Arnott (1980) and Stroud & Millane (1995).

Fibres are also subject to orientational disorder. The polymer helices in noncrystalline fibres and the microcrystallites in crystalline fibres are not perfectly aligned to the fibre axis; the deviation from parallelism is called the disorientation of the fibre. Disorientation causes the reflections from crystalline fibres and the diffracted intensity from noncrystalline fibres to be spread into arcs (Debye–Scherrer arcs).

19.5.3. Diffraction by helical molecules

19.5.3.1. Fibre diffraction patterns

As noted above, the diffraction pattern from a fibre is confined to layer lines because of the repeating nature of the polymer helix. The layer lines in reciprocal space are perpendicular to the fibre axis in real space. The layer line passing through the origin in reciprocal space is called the equator or zero layer line. The line in a diffraction pattern normal to the equator and passing through the origin is called the meridian. If the fibre axis is perpendicular to the incident X-ray beam, the recorded diffraction pattern is symmetric about both the equator and the meridian. If the fibre is not normal to the incident beam, the pattern is symmetric only about the meridian.

19.5.3.2. Helical symmetry

It is convenient to use cylindrical coordinates to describe helical molecules. In real space we use coordinates (r, φ, z); in reciprocal space (R, ψ, Z). By convention, the z axis is the helix axis and the line $(\varphi = 0, z = 0)$ corresponds to the x axis in Cartesian coordinates. The repeat distance along the z axis is c. Within this distance, there are u repeating units in t turns of the helix. If the coordinates of a point in the first repeating unit are (r, φ, z), then applying the helical symmetry gives the coordinates of the corresponding point in the $(k + 1)$th repeating unit as $(r, \varphi + 2\pi kt/u, z + kc/u)$.

19.5.3.3. Structure factors

Cochran *et al.* (1952) showed that the structure factor on layer line l of a helix made up of repeating subunits is

$$\mathbf{F}(R,\psi,Z) = \sum_j \sum_n f_j J_n(2\pi R r_j) \exp\{i\,[n(\psi + \pi/2) - n\varphi_j + 2\pi l z_j/c]\}. \tag{19.5.3.1}$$

Diffraction occurs only for $Z = l/c$. r_j, φ_j and z_j are the real-space coordinates of atom j in the repeating unit of the helix; f_j is the atomic scattering factor of that atom. J_n is the Bessel function of the first kind of order n. The summation over n includes only those values of n that satisfy the selection rule

$$l = tn + um, \tag{19.5.3.2}$$

where m is any integer. In practice, the summation may be limited to values of $|n|$ less than $2\pi r_{\max} R + 2$, where $r_{\max}$ is the radius of the outermost atom in the polymer, because the value of a Bessel function $J_n(x)$ is negligible for n greater than about $x + 2$. For low-order Bessel functions or applications requiring greater accuracy, slight variations of this limitation are used.

The structure factor **F** is a complex number with an amplitude and phase, and is fully equivalent to that derived using the trigonometric functions in crystallography. The expression for intensity $I = \mathbf{F}\mathbf{F}^* = |\mathbf{F}|^2$ holds good.

Equation (19.5.3.1) can be rewritten (Klug *et al.*, 1958) as

$$\mathbf{F}(R, \psi, l/c) = \sum_n \mathbf{G}_{n,l}(R) \exp[in(\psi + \pi/2)], \tag{19.5.3.3}$$

where the Fourier–Bessel structure factor $\mathbf{G}_{n,l}(R)$ is independent of ψ and is given by

$$\mathbf{G}_{n,l}(R) = \sum_j f_j J_n(2\pi R r_j) \exp[i(-n\varphi_j + 2\pi l z_j/c)]. \tag{19.5.3.4}$$

$J_n(0)$ is 1 when $n = 0$ and 0 otherwise. For this reason, the structure factors on the meridian $(R = 0)$ are nonzero only on layer lines for which l is an integral multiple of u. Hence, a visual inspection of the diffraction pattern often helps to determine u.

19.5.3.4. Fourier–Bessel syntheses

Electron densities may be calculated for crystalline fibres, as they are in crystallography, using Fourier syntheses with coefficients determined for the crystalline reflections.

For noncrystalline fibres, it is more convenient to use Fourier–Bessel syntheses: the electron density ρ at point (r, φ, z) is

$$\rho(r, \varphi, z) = (1/c) \sum_l \sum_n \mathbf{g}_{n,l}(r) \exp[i(n\varphi - 2\pi l z/c)], \tag{19.5.3.5}$$

where

$$\mathbf{g}_{n,l}(r) = \int_0^\infty \mathbf{G}_{n,l}(R) J_n(2\pi R r) 2\pi R \,\mathrm{d}R. \tag{19.5.3.6}$$

19.5.3.5. Diffracted intensities: noncrystalline fibres

The intensity in the diffraction pattern of a noncrystalline fibre is the cylindrical average of the square of the Fourier transform (Franklin & Klug, 1955):

$$\begin{aligned} I(R, l) &= \langle |\mathbf{F}(R, \psi, l/c)|^2 \rangle_\psi \\ &= \sum_n \mathbf{G}_{n,l}(R)\mathbf{G}^*_{n,l}(R) \\ &= \sum_n |\mathbf{G}_{n,l}(R)|^2. \end{aligned} \tag{19.5.3.7}$$

The intensity varies continuously as a function of R along each layer line (Fig. 19.5.2.1*a*).

19.5.3.6. Diffracted intensities: polycrystalline fibres

The intensity in the diffraction pattern of a polycrystalline fibre consists of Bragg reflections on layer lines (Fig. 19.5.2.1*b*). On each layer line, owing to the lattice sampling that arises from the lateral organization of the polymers, intensities are observed at discrete R values defined by the reciprocal-lattice points. In the case of monoclinic (with c as the unique axis), orthorhombic and hexagonal systems, the reflection positions are determined by equations (19.5.3.8), (19.5.3.9) and (19.5.3.10), respectively.

$$R_{hk}^2 = h^2a^{*2} + k^2b^{*2} + 2hka^*b^*\cos\gamma^*, \qquad (19.5.3.8)$$

$$R_{hk}^2 = h^2a^{*2} + k^2b^{*2}, \qquad (19.5.3.9)$$

$$R_{hk}^2 = (h^2 + k^2 + hk)a^{*2}. \qquad (19.5.3.10)$$

Consequently, on each layer line, superposition occurs between reciprocal-lattice points (hkl) and $(\bar{h}\bar{k}l)$ for monoclinic; (hkl), $(\bar{h}kl)$, $(h\bar{k}l)$ and $(\bar{h}\bar{k}l)$ for orthorhombic; and (hkl), $(\bar{h}\bar{k}l)$, (khl), $(\bar{k}\bar{h}l)$, (kil), $(\overline{ki}l)$, (ikl), $(\overline{ik}l)$, (ihl), $(\overline{ih}l)$, (hil) and $(\overline{hi}l)$, where $i = -(h + k)$, for hexagonal systems. Depending upon the unit-cell dimensions, other reflections having the same R value may also be superposed to give a single intensity, and those having R values close to each other may be difficult to resolve. All superposed reflections must be considered individually when calculating such composite intensities.

19.5.4. Fibre preparation

Natural fibre specimens may require only the selection of fibres or regions of fibres in which the polymers are well oriented, but many other fibres must be made in the laboratory, and orientation can often be improved by a wide variety of procedures.

Orientation often requires controlled conditions of relative humidity and temperature during the preparation of the fibre; in many cases, these conditions must be maintained during data collection. In some cases, tension must be applied to the fibres; in an increasing number of cases, magnetic fields have been found to improve orientation. Fibres may be drawn directly from concentrated polymer solutions or made by stretching gels, using weights to stretch strips of polymer films cast on Teflon blocks or applying radial heating while forming polymer films (Arnott, Guss *et al.*, 1974; Chandrasekaran, Radha, Lee & Zhang, 1994). A drop of concentrated polymer solution may simply be dried while suspended between two supports (McDonald *et al.*, 2008). Magnetic fields have dramatically improved the orientation in dried fibres of polymers having significant dipole moments (Torbet, 1987).

Oriented sols, generally enclosed in glass capillaries, are usually made using shearing forces, either by moving the sol in the capillary (Gregory & Holmes, 1965; Kendall & Stubbs, 2006) or by centrifugation (Cohen *et al.*, 1971). Again, magnetic fields can greatly improve orientation, sometimes in combination with centrifugation (Yamashita, Suzuki & Namba, 1998).

Any of these stretching or orienting processes might facilitate the growth of long microcrystallites along the fibre axis. Crystallization in general and lateral organization in particular are achieved primarily by careful choice of solution conditions, including solvent, pH, additives, relative humidity and temperature. In both crystalline and noncrystalline specimens, annealing processes are often important to both crystallization and orientation.

19.5.5. Data collection

Fibre-diffraction data were historically collected using laboratory X-ray sources and photographic film, but synchrotron sources (Shotton *et al.*, 1998) are now generally used for final data collection (Janaswamy & Chandrasekaran, 2005, 2006; Tsuruta & Irving, 2008), taking advantage of reduced exposure time, the potential for time-resolved studies and the fact that many fibres (or the well oriented regions of fibres) are too small for laboratory data collection. Charge-coupled device (CCD) detectors have largely replaced film. Pinhole cameras, mirror-monochromator optics and double-mirror optics are used in different applications. Diffraction by most fibres is inherently weak, and very long repeat distances often require long distances between the specimen and the detector, so fibre cameras are often flushed with helium or kept under vacuum to reduce air scatter. Constant relative humidity is often required, and is achieved by bubbling a helium stream through a saturated salt solution followed by a salt trap or by isolating the sample in equilibrium with a saturated salt solution (McDonald *et al.*, 2008).

The X-ray beam commonly strikes a stationary fibre perpendicular to the fibre axis. Because of the cylindrical averaging of the data, this procedure allows most of the diffraction pattern to be collected in a single exposure. There is, however, a ‘blind region’ around the meridian, where the Ewald sphere does not intersect the diffraction pattern (Fraser *et al.*, 1976). Data in this region are collected by tilting the fibre.

19.5.6. Data processing

19.5.6.1. *Coordinate transformation*

Data must be transformed from detector space into reciprocal space (Fraser *et al.*, 1976). Transformation of coordinates requires determination of the origin of the diffraction pattern in detector space, the fibre tilt angle β, the twist angle (often called in-plane tilt, the inclination of the projection of Z along the beam to the detector coordinate system) and the specimen-to-detector distance. It may also require determination of the detector missetting angles (the deviation of the normal to the detector plane from the beam). All of these parameters can be determined by comparing equivalent reflections in the diffraction pattern.

Most data-processing programs determine the transformation parameters by some form of minimization of the deviation from equivalence in the positions of well resolved equivalent reflections. The tilt was traditionally determined by comparing the apparent Z values of equivalent reflections, but the apparent value of R for near-meridional reflections is much more sensitive to tilt. The minimization set should therefore include some near-meridional reflections if the tilt value is to be determined accurately. The helical repeat distance and, for polycrystalline fibres, the unit-cell parameters must also be determined at this time, but helical repeat distance and specimen-to-detector distance are so highly correlated that it is not often practical to refine both. Data may be visualized and in many cases transformed and processed using a number of software applications, including the programs *WCEN* (Bian *et al.*, 2006), *FibreFix* (Rajkumar *et al.*, 2005) and *FIT2D* (http://www.esrf.eu/computing/scientific/FIT2D).

19.5.6.2. *Intensity correction*

Data intensities must be corrected for geometric and polarization effects (Fraser *et al.*, 1976; Millane & Arnott, 1986). The geometric correction has two components: a factor due to the geometry of the intersection between the diffraction pattern in reciprocal space and the sphere of reflection, and a factor due to the angle of incidence of the diffracted beam on the detector. The first factor is analogous to the Lorentz factor in crystallography, which arises because of the time taken for a reflection from a moving sample to pass through the Ewald sphere. The geometric correction can be applied to each data point as a single correction (Fraser *et al.*, 1976). For both crystalline and noncrystalline fibres, it has often been convenient to integrate reflections or arcs before applying Lorentz and polarization corrections, or to apply some corrections before integration and some after (Millane &

Arnott, 1986), but this practice is decreasing as computational power increases. The Lorentz correction for crystalline fibres is

$$1/L = 2\pi \sin\theta\,[\cos^2\theta\cos^2\beta - (\cos\sigma - \sin\theta\sin\beta)^2]^{1/2}, \quad (19.5.6.1)$$

where θ is the Bragg angle and $\tan\sigma = R/Z$ (Millane & Arnott, 1986). The polarization correction for an unpolarized X-ray beam is

$$p = (1 + \cos^2 2\theta)/2. \quad (19.5.6.2)$$

For a polarized beam, such as a synchrotron beam, the expression for p is more complicated (Azároff, 1955; Kahn *et al.*, 1982; Bian *et al.*, 2006). Intensities should be divided by Lp. Intensities may also be corrected for nonlinearity of detector response and for absorption by the specimen and by detector components.

19.5.6.3. Background subtraction

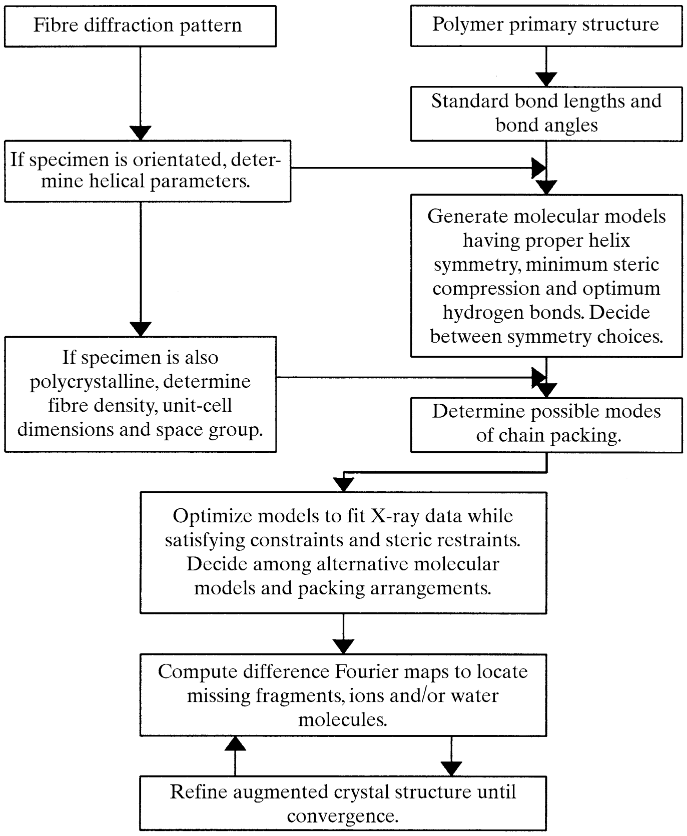
The background can be very high in fibre-diffraction data because of long exposure times and scattering from amorphous material. Because of specimen disorientation, fibre-diffraction data often contain large regions where there is no space between layer lines, so local-background-fitting methods are rarely useful. The background may be determined by fitting an analytical function to intensities at points between reflections (Millane & Arnott, 1985; Lorenz & Holmes, 1993), or by fitting a function that includes both signal and background components to the reflection data. This type of profile fitting has been described for individual reflections (Fraser *et al.*, 1976), for data in concentric rings about the centre of the diffraction pattern (Makowski, 1978) and for entire data sets (Yamashita *et al.*, 1995; Ivanova & Makowski, 1998).

19.5.6.4. Integration of crystalline fibre data

The variation of reflection shape in detector space can be determined using a few sharp reflections and taking into account parameters related to crystallite size and disorientation in the specimen (Millane & Arnott, 1986). This allows the integration boundary of a reflection to be determined. Sometimes, the boundary encompasses two or more reflections too close to separate; such reflections are considered to constitute a composite reflection.

19.5.6.5. Integration of continuous data

In diffraction from noncrystalline fibres, intensity is a function of R on each layer line. Angular deconvolution (Makowski, 1978; Namba & Stubbs, 1985; Yamashita *et al.*, 1995) or profile fitting (Millane & Arnott, 1986) corrects for disorientation and overlap between adjacent layer lines and may also incorporate background subtraction. The intensity determined in this way should be corrected for geometric and other effects if this has not been done previously (Section 19.5.6.2; Namba & Stubbs, 1985; Millane & Arnott, 1986).



Fibre diffraction pattern
Polymer primary structure
Standard bond lengths and bond angles
If specimen is orientated, determine helical parameters.
Generate molecular models having proper helix symmetry, minimum steric compression and optimum hydrogen bonds. Decide between symmetry choices.
If specimen is also polycrystalline, determine fibre density, unit-cell dimensions and space group.
Determine possible modes of chain packing.
Optimize models to fit X-ray data while satisfying constraints and steric restraints. Decide among alternative molecular models and packing arrangements.
Compute difference Fourier maps to locate missing fragments, ions and/or water molecules.
Refine augmented crystal structure until convergence.

Figure 19.5.7.1
Flow chart of the principal steps in the determination and refinement of fibre structures with small unit cells.

19.5.7. Determination of structures

If the amplitude and phase of each diffracted wave are known, structure determination is, in principle, straightforward (Section 19.5.3.4). In practice, however, the phase problem for fibres is more acute than for single crystals because of the limited resolution of the data, and because the diffracted intensities overlap as a result of disorientation and cylindrical averaging. Patterson methods (MacGillavry & Bruins, 1948; Stubbs, 1987) have sometimes been useful, but the cylindrically averaged Patterson function is usually too complicated for detailed interpretation. Phasing by heavy-atom methods is not practical for polymers with small unit cells because of the difficulties in incorporating heavy atoms into the structures. Structures having small unit cells are instead determined by constructing initial models based on chemical information and the observed helical parameters. Extensions of the isomorphous-replacement method (Namba & Stubbs, 1985) have been useful in determining structures, such as those of helical viruses, in which the unit cells are much larger. In all cases, refinement and evaluation of the model structures are essential. A flow chart of the sequential steps in the determination and refinement of fibre structures with small unit cells is shown in Fig. 19.5.7.1.

19.5.7.1. Initial models: small unit cells

For many biopolymers, especially polypeptides, polynucleotides and polysaccharides, the repeating unit is a monomer or a small oligomer and the unit-cell dimensions are in the range 10 to 50 Å. Such unit cells can accommodate one or more polymer helices, packed in an organized fashion.

An initial model is constructed from the primary structure of the repeating unit, using bond lengths, bond angles and some conformation angles derived from surveys of accurate single-crystal analyses. The model must satisfy the observed helical parameters and have reasonable intra- and inter-chain nonbonded, hydrogen-bonded and polar interactions.

This preliminary model provides an approximate solution to the phase problem and a starting point for refinement. Since there is no assurance that the refined model represents the true structure, however, stereochemically plausible alternatives must be carefully considered, refined and objectively adjudicated.

Alternatives can include both right- and left-handed helices, single helices, and multistranded helices with parallel and antiparallel strands. The next stage involves the packing arrangement in the unit cell. If two or more helices are present, their positions, orientations and relative polarities must be varied in refinement.

19.5.7.2. Refinement: small unit cells

The widely used linked-atom least-squares (*LALS*) technique (Arnott & Wonacott, 1966; Smith & Arnott, 1978) and the variable virtual bond (*PS79*) method (Zugenmaier & Sarko, 1980) were developed for fibre structures. They are similar in principle to the least-squares refinement procedure for crystalline proteins (Hendrickson, 1985), although bond lengths and bond angles are usually kept fixed in the fibre refinements. The function minimized by the *LALS* program is of the form

$$\Omega = \sum_m w_m \Delta F_m^2 + \sum_i e_i \Delta\theta_i^2 + \sum_j k_j \Delta c_j^2 + \sum_n \lambda_n G_n. \qquad (19.5.7.1)$$

The first term on the right-hand side is the weighted sum of the squares of the differences, ΔF_m, between observed and calculated X-ray structure amplitudes of Bragg reflections or continuous diffraction. Either or both types of data can be used as necessary. The weights, w_m, are inversely proportional to the estimated variance of the data. The second term minimizes the differences, $\Delta\theta_i$, between the expected (standard) values of conformation and bond angles and those in the model; the weights, e_i, are based on empirically determined variances. The third term is designed to take care of non-bonded interactions and thus keep the model free from steric compression. It includes the deviations from target values of both intra- and inter-chain hydrogen bonds and the differences between acceptable and calculated non-bonded distances for those contacts that are smaller than the acceptable limiting values. The weights, k_j, are based on the Buckingham energy function for non-bonded contacts and empirical variances for hydrogen bonds. Finally, the fourth term imposes constraints (G_h, with Lagrange multipliers λ_h) for helix connectivity and ring closure, as in a furanose or pyranose, and it vanishes when all such constraints are satisfied. During the refinement, the structure factors are calculated with either the conventional atomic scattering factor f or with a solvent-corrected atomic scattering factor f_w (Fraser *et al.*, 1978; Chandrasekaran & Radha, 1992) given by the function

$$f_w(D) = f(D) - v\sigma_s \exp(-\pi v^{2/3} D^2), \qquad (19.5.7.2)$$

where $D = (R^2 + Z^2)^{1/2}$, σ_s is the electron density of the solvent and v is the excluded volume of the atom. If the van der Waals radius of water is taken as 2 Å, σ_s for water is 0.2984 e Å^{-3}. Equation (19.5.7.2) allows for the solvent contribution to the diffracted intensity and is particularly useful in studying hydrated fibres in which structured and amorphous water can account for up to 50% of the total mass.

19.5.7.3. Data-to-parameter ratio

The total number of data used in this refinement process is $M + I + J$, where M, I and J are, respectively, the number of observations in the first three terms of equation (19.5.7.1). If P is the number of parameters refined and H is the number of independent constraints in the last term, then the number of degrees of freedom of the system is $P - H$. The effective number of data is given by $D = (M + I + J) - (P - H)$. The data-to-parameter ratio (*D/P*), a measure of the dependability of the final results, must be greater than one for meaningful refinement. *D/P* is typically in the range 3 to 11 in the analysis of polynucleotide and polysaccharide structures. This ratio is comparable to those commonly reported for single-crystal structures, confirming that fibre-diffraction analysis of polymers, despite the limited number of X-ray data, can yield reliable results.

19.5.7.4. Initial models: large unit cells

For large macromolecular aggregates, such as viruses and cytoskeletal filaments, initial models cannot usually be devised using the primary structure of the molecule alone. The largely α-helical filamentous bacteriophages form a rare class of exceptions (Makowski *et al.*, 1980). Molecular-replacement methods, in which initial models are constructed from single-crystal structure determinations of the separated components of the aggregate or from known related structures, can be useful, but because of the limited number of data in a fibre pattern such models can sometimes be difficult to refine.

Multi-dimensional isomorphous replacement (MDIR), an extension of the isomorphous-replacement method of protein crystallography, has been useful in studying helical viruses (Stubbs & Diamond, 1975; Namba & Stubbs, 1985). The dimensions are the real and imaginary parts of the various overlapping structure factors at a given point in the diffraction pattern. Information about both the phases of the structure factors and the relative magnitudes of the overlapping structure factors is obtained from heavy-atom derivatives of the virus; at least twice as many heavy-atom derivatives as the number of significant **G** terms in equation (19.5.3.7) are required. If the structure of a related aggregate is known, MDIR can be combined with molecular replacement (Namba & Stubbs, 1987*a*; Wang & Stubbs, 1994); in this case, fewer derivatives are required.

Layer-line splitting (Franklin & Klug, 1955) arises when the helical symmetry of the scattering particles is close to, but not exactly, integral. For example, tobacco mosaic virus (TMV) has 49.02 subunits in three turns of the viral helix. In this case, the **G** terms in each layer line do not fall at exactly the same Z values in the diffraction pattern. The resulting shifts in the positions of the layer lines can be measured for the native aggregate and, in favourable cases, for heavy-atom derivatives, and used to provide additional phase information (Stubbs & Makowski, 1982). Information from electron microscopy (Beese *et al.*, 1987) and neutron scattering (Nambudripad *et al.*, 1991) has also been used.

19.5.7.5. Refinement: large unit cells

Refinement of fibre structures having large unit cells has many parallels to refinement in protein crystallography. Refinement in real space, especially the solvent-flattening approach, has been widely used to improve electron-density maps and is particularly valuable in structure determination of noncrystalline fibres. Since helical aggregates have finite radii, **g** terms [equation (19.5.3.6)] can be set to zero outside a maximum radius and back-transformed to obtain refined estimates of the phases of the **G** terms. More detailed solvent-flattening algorithms can also be used (Namba & Stubbs, 1985).

Molecular models can be refined by methods conceptually related to those of *LALS*. The principal difference is that bond lengths and angles are not kept fixed, but are restrained to remain close to standard values. The restrained least-squares method (Hendrickson, 1985), widely used in protein crystallography, has been adapted (Stubbs *et al.*, 1986) for fibre diffraction and used to refine a number of filamentous virus structures (Namba *et al.*, 1989; Nambudripad *et al.*, 1991). Although effective, the radius of convergence of this method is less than desired, probably because of the limited number of data available from fibre diffraction (Wang & Stubbs, 1993).

Molecular-dynamics methods have been used to increase the radius of convergence of refinement (Wang & Stubbs, 1993). The program *X-PLOR* (Brünger *et al.*, 1987) has been adapted for fibre diffraction and can handle data from both crystalline and noncrystalline fibres. A potential-energy function of the form

$$\Omega = E + S \sum_{l} \sum_{i} w_{li} \{[I_o(R_i)]^{1/2} - [I_c(R_i)]^{1/2}\}^2 \qquad (19.5.7.3)$$

is minimized. The first term, E, is an empirical energy function that accounts for distortions in bond lengths, bond angles and conformation angles, and for non-bonded, electrostatic and hydrogen-bonding interactions. The second term accounts for the differences between the observed and calculated X-ray intensities at specific values of R_i on every layer line l; w_{li} is the weight for each observation and S is a normalizing factor. In the most effective use of this method, simulated annealing, the process of heating the structure to a temperature of 3000 to 4000 K is simulated, and then the structure is cooled ('annealed') in small increments. At high temperatures, energy barriers between the starting model and structures of lower potential can be overcome; in this way, the radius of convergence of the refinement is increased.

19.5.7.6. Difference Fourier methods

As in crystallography, difference maps are used during refinement to correct errors and to identify missing fragments of the model and, in the final stages of refinement, to identify solvent molecules and associated ions.

In crystalline fibre diffraction, the most common difference maps use calculated phases with amplitudes of either $F_o - F_c$ or $2F_o - F_c$. In both cases, weighting the coefficients on the basis of the observed and calculated structure amplitudes has been used to minimize the root-mean-square error in the electron-density maps. Reflections superposed by cylindrical averaging do, however, present problems. One solution is to divide the observed intensity equally among the superposed reflections. This is a reasonable approach in the initial stages of structure analysis, when the reliability of the model is uncertain, and has the advantage of minimizing bias toward the model. Alternatively, the observed intensity may be split in the same ratio as the calculated intensity. This approach, although biased, is more effective for locating solvent molecules and ions in an otherwise well determined structure. Difference Fourier maps have played a significant role in determining the molecular structures and packing arrangements in unit cells mediated by water molecules and cations of several polynucleotide (Chandrasekaran *et al.*, 1995, 1997) and polysaccharide helices (Winter *et al.*, 1975; Chandrasekaran *et al.*, 1988, 1998; Chandrasekaran, Radha & Lee, 1994; Janaswamy & Chandrasekaran, 2001, 2002, 2008).

In noncrystalline fibre diffraction, the superposition of intensities due to cylindrical averaging is more serious and must be taken into account. Namba & Stubbs (1987*b*) have shown that the coefficients yielding the most accurate electron-density maps of the full structure have amplitudes of $NG_o - (N-1)G_c$, where N is the number of significant terms in equation (19.5.3.7) (the number of superposed intensities), and the observed intensity is divided in the ratio of the calculated intensity. For filamentous viruses at moderate resolution, N is typically in the range four to six. As in crystallography and crystalline fibre diffraction, maps calculated from amplitudes of $F_o - F_c$ have low noise levels and are most useful for checking the accuracy of final models and for locating solvent molecules.

19.5.7.7. Evaluation

As in crystallography, fibre structures are evaluated by statistical measures, such as R values, and by the examination of difference maps. Fibre-diffraction R values are inherently lower than those expected in crystallography, particularly when large numbers of intensities have been superposed by cylindrical averaging (Stubbs, 1989). The largest likely R value for noncrystalline TMV at 3 Å resolution is about 0.31 and for polycrystalline DNA at 3 Å resolution it is about 0.41, both significantly less than the value of 0.59 to be expected from noncentric single-crystal analyses (Millane, 1989). Free R values, widely used in crystallography, have been used to a limited extent in fibre diffraction (Welsh *et al.*, 2000), sometimes with modifications to deal with the effect of overlapping Bessel orders (Welsh *et al.*, 1998). Some authors prefer to use correlation coefficients to evaluate models.

Comparison of R values alone is not necessarily a reliable way to discriminate between competing models. Such discrimination is often required for structures with small unit cells, for which alternative models are routinely refined (Sections 19.5.7.1 and 19.5.7.2). The relative merits of any pair of competing models can be assessed on the basis of several types of statistics (Arnott, 1980) using Hamilton's significance test (Hamilton, 1965), which considers not only residuals but also numbers of degrees of freedom (Section 19.5.7.3). Such a test is essential. There are many examples in the literature where R values have been lowered by the simple process of increasing the number of degrees of freedom; a decreased R value obtained in this way may or may not have any significance.

Difference Fourier maps have been used to evaluate crystalline fibre diffraction analyses for many years, for example, to reject the controversial Hoogsteen base pairing in double-stranded DNA (Arnott *et al.*, 1965), and later to discriminate between 10- and 11-fold double helices of RNA (Arnott *et al.*, 1967). Difference maps have been essential in the refinement of fibre structures with large unit cells (Namba *et al.*, 1989; Wang & Stubbs, 1994), both to identify errors in early models and to confirm that the final structures contained no major errors or omissions.

19.5.8. Structures determined by X-ray fibre diffraction

The α-helix of several synthetic polypeptides (Pauling & Corey, 1951), the double helix of DNA (Franklin & Gosling, 1953*a*,*b*; Watson & Crick, 1953), the ribbon structure of cellulose (Meyer & Misch, 1937) and the low-resolution structure of tobacco mosaic virus (Barrett *et al.*, 1971) were early examples of structures determined by fibre diffraction. Early workers also examined a number of fibrous proteins (Bailey *et al.*, 1943). In the past 50 years, developments in theory and practice and the availability of fast computers have made it possible to determine and refine about 200 biological polymer structures of varying complexities. The largest repeating units in polypeptides, polynucleotides and polysaccharides solved to date correspond to a tripeptide, a tetranucleotide and a heptasaccharide, respectively.

19.5.8.1. Polypeptides

The structural details of the α-helix and β-sheet, the principal secondary-structure elements of proteins, have emerged from the analysis of synthetic polypeptides (Pauling & Corey, 1951, 1953).

Analysis of noncrystalline fibre-diffraction patterns led to the triple-helical coiled-coil model of collagen (Ramachandran & Kartha, 1955; Rich & Crick, 1955). There have been many recent studies on amyloid fibrils, associated with a large number of diseases including Alzheimer's and Parkinson's diseases, and including peptide fragments of prions, infectious amyloids associated with diseases such as bovine spongiform encephalopathy ('mad cow disease') (Inouye *et al.*, 1993, 2000; Malinchik *et al.*, 1998; Kishimoto *et al.*, 2004; Makin & Serpell, 2005).

19.5.8.2. Polynucleotides

The molecular structures of a series of DNA and RNA helices have been determined and refined using data from polycrystalline fibres (Arnott *et al.*, 1969; Chandrasekaran & Arnott, 1989). These include the canonical A, B and C forms of DNA, corresponding, respectively, to 11-, 10- and 9.3-fold right-handed antiparallel Watson–Crick base-paired helices. Structural differences between the three have been attributed to changes in furanose puckerings and helical parameters: the A form has C3-*endo*, but B and C have C2-*endo* or analogous C3-*exo* puckers. All RNA duplexes are members of the A family. Later important structures included the sixfold single helix of poly (C) (Arnott *et al.*, 1976), a compact eightfold double helix for poly d(AT) and poly d(IC) (Arnott *et al.*, 1983), and the left-handed Z-DNA for poly d(GC) (Arnott *et al.*, 1980). Difference Fourier syntheses were instrumental in locating a spine of water molecules in the minor groove and a series of sodium ions and water molecules that bridge the phosphate groups of adjacent DNA molecules in the tenfold helices of poly (dA)·poly (dT) (Chandrasekaran *et al.*, 1995), poly (dA)·poly (dU) and poly d(AI)·poly d(CT) (Chandrasekaran *et al.*, 1997). Neutron fibre diffraction has been particularly useful for locating water molecules in polynucleotides (Shotton *et al.*, 1997, 1998). Data from noncrystalline fibres have been used to determine, among others, the structures of DNA·RNA hybrid duplexes (Arnott *et al.*, 1986), a DNA triple-stranded helix (Chandrasekaran *et al.*, 2000*a*) and two RNA triple-stranded helices (Chandrasekaran *et al.*, 2000*b*,*c*).

19.5.8.3. Polysaccharides

Among the three-dimensional structures determined for industrially useful and biologically important polysaccharides are the gel-forming calcium *i*-carrageenan (Arnott, Scott *et al.*, 1974; Janaswamy & Chandrasekaran, 2001, 2002, 2008), sodium pectate (Walkinshaw & Arnott, 1981), gellan (Chandrasekaran *et al.*, 1988) and welan (Chandrasekaran, Radha & Lee, 1994), and a series of distinct helical forms of the glycosaminoglycan hyaluronan (Arnott & Mitra, 1984). The conformations of these molecules are delicately controlled by ions, such as sodium, potassium and calcium. The repeating units range from a simple monosaccharide to a branched pentasaccharide.

Specific interactions among the polysaccharides and their associated small molecules can be correlated with their observed properties. A number of neutral polysaccharides, such as cellulose, chitin and mannan, are twofold ribbon-like helices, which aggregate and are hence water insoluble. The *A* and *B* forms of amylose, the main constituents of starch granules, are sixfold left-handed parallel double helices. Derivatization of amylose leads to the formation of single helices (Chandrasekaran, 1997). The water-soluble galactomannan derives its high viscosity in aqueous solution from intermolecular side-chain interactions (Chandrasekaran *et al.*, 1998). Gels of calcium iota-carrageenan are stronger owing to more intimate sulfate-group interactions between double helices than in the sodium form (Janaswamy & Chandrasekaran, 2001, 2002, 2008).

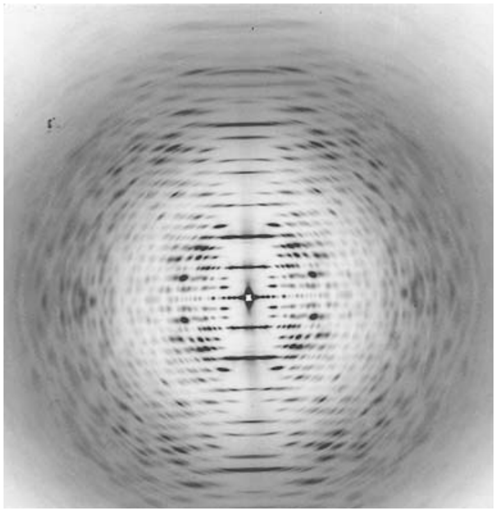


Figure 19.5.8.1
X-ray diffraction pattern from an oriented sol of the U2 strain of tobacco mosaic virus.

19.5.8.4. Helical viruses and bacteriophages

The largest repeating units in structures determined by fibre diffraction are those of several members of the tobamovirus family, including tobacco mosaic virus (Namba *et al.*, 1989; Kendall *et al.*, 2007), cucumber green mottle mosaic virus (Wang & Stubbs, 1994) and ribgrass mosaic virus (Wang *et al.*, 1997). These viruses are rod-shaped, 3000 Å long and about 180 Å in diameter. Oriented sols yield exceptionally good diffraction patterns (Fig. 19.5.8.1). The asymmetric unit consists of a protein subunit of approximate molecular weight 18 000 Da and three nucleotides of RNA. The coat proteins are folded like globular proteins and are about 40% α-helical, with small regions of β-sheet. All of the amino acids, all three nucleotides, and in some cases water molecules and calcium ions, are seen in the electron-density maps. The TMV structure was determined by MDIR; the remaining structures were determined by molecular replacement from TMV or by a combination of molecular replacement and isomorphous replacement. All of the structures were refined by restrained least-squares or molecular-dynamics methods to *R* values of less than 0.10 at resolutions between 2.9 and 3.5 Å. Fibre diffraction data from a number of flexible filamentous viruses, including members of the *Flexiviridae* and *Potyviridae* families, have been used in conjunction with data from electron cryomicroscopy to determine symmetries and low-resolution structures (Kendall *et al.*, 2008).

Several filamentous bacteriophage structures, including fd, Pf1 and related strains, have been determined and refined. Filamentous bacteriophages are flexible viruses, about 60 Å in diameter and 10 000 to 20 000 Å in length. Several thousand copies of a coat protein of about 50 residues wrap around a central single-stranded circular DNA. The DNA does not appear to be sufficiently ordered to appear in electron-density maps. The coat-protein molecules have an unusually simple structure, being almost entirely α-helical (Marvin *et al.*, 1974). Model-building approaches have therefore been used, sometimes supplemented by isomorphous replacement (Bryan *et al.*, 1983). Neutron scattering from bacteriophages with selectively deuterated amino-acid residues has also been used to assist model building

(Nambudripad *et al.*, 1991). Both restrained least-squares (Nambudripad *et al.*, 1991) and molecular-dynamics (Gonzalez *et al.*, 1995) refinement methods have been used. The coat protein forms two α-helical layers (Welsh *et al.*, 1998).

19.5.8.5. Other large assemblies

Low-resolution X-ray fibre-diffraction data have been successfully used to model the structural details of a number of complex assemblies. For example, the structure of the F-actin helix at 8 Å resolution has been described by combining the single-crystal structure of the G-actin monomer with fibre-diffraction data (Holmes *et al.*, 1990; Oda *et al.*, 2009). This structure, in turn, has been used to model the muscle thin filament, composed of F-actin monomers and tropomyosin, at about 25 Å resolution, both in the resting and activated states, and hence to understand the movement of tropomyosin in muscle function (Squire *et al.*, 1993). The structure of the microtubule has been determined at 18 Å resolution using information from electron microscopy and fibre diffraction (Beese *et al.*, 1987). A similar but more sophisticated approach was used for bacterial flagellar filaments at 9 Å resolution (Yamashita, Hasegawa *et al.*, 1998); the diffraction patterns obtained from these filaments are of such high quality that prospects for a complete molecular structure are excellent.

Chapter 19.6. Electron cryomicroscopy of biological macromolecules

T. S. Baker and R. Henderson

19.6.1. Abbreviations used

0D	Zero-dimensional (single particles)
1D	One-dimensional (helical)
2D	Two-dimensional
3D	Three-dimensional
EM	Electron microscope/microscopy
CryoTEM	Transmission electron cryomicroscopy
FEG	Field-emission gun
CTF	Contrast-transfer function
MTF	Modulation transfer function
DQE	Detective quantum efficiency
DPR	Differential phase residual
FSC	Fourier shell correlation
CCD	Charge-coupled device (slow-scan TV detector)

19.6.2. Introduction: macromolecular structure determination using electron microscopy

The two principal methods of macromolecular structure determination that use scattering techniques are electron microscopy and X-ray crystallography. The most important difference between the two is that the scattering cross section is about 10^5 times greater for electrons than it is for X-rays, so significant scattering using electrons is obtained for specimens that are 1 to 10 nm thick, whereas scattering or absorption of a similar fraction of an illuminating X-ray beam requires crystals that are 100 to 500 µm thick, though in recent years smaller crystals, still > 1 µm thick, have become usable at synchrotron sources. The second main difference is that electrons are much more easily focused than X-rays since they are charged particles that can be deflected by electric or magnetic fields. As a result, electron lenses are much superior to X-ray lenses and can be used to produce a magnified image of an object as easily as a diffraction pattern. This allows the electron microscope to be switched back and forth instantly between imaging and diffraction modes so that the image of a single molecule at any magnification can be obtained as conveniently as the electron-diffraction pattern of a thin crystal.

In the early years of electron microscopy of macromolecules, electron micrographs of molecules embedded in a thin film of heavy-atom stains (Brenner & Horne, 1959; Huxley & Zubay, 1960) were used to produce pictures which were interpreted directly. Beginning with the work of Klug (Klug & Berger, 1964), a more rigorous approach to image analysis led first to the interpretation of the two-dimensional (2D) images as the projected density summed along the direction of view and then to the ability to reconstruct the three-dimensional (3D) object from which the images arose (DeRosier & Klug, 1968; Hoppe *et al.*, 1968), with subsequent more sophisticated treatment of image contrast transfer (Erickson & Klug, 1971).

Later, macromolecules were examined by electron diffraction and imaging without the use of heavy-atom stains by embedding the specimens in either a thin film of glucose (Unwin & Henderson, 1975) or in a thin film of rapidly frozen water (Taylor & Glaeser, 1974; Dubochet *et al.*, 1982, 1988), which required the specimen to be cooled while it was examined in the electron microscope. This use of unstained specimens thus led to the structure determination of the molecules themselves, rather than the structure of a ‘negative stain’ excluding volume, and has created the burgeoning field of 3D electron microscopy of macromolecules.

Many medium-resolution (*i.e.*, 5–15 Å) structures of macromolecular assemblies (*e.g.* ribosomes), spherical and helical viruses, and larger protein molecules have now been determined by transmission electron cryomicroscopy (cryoTEM) in ice. A small number of atomic resolution structures have been obtained by cryoTEM of thin 2D crystals embedded in glucose, trehalose or tannic acid (Henderson *et al.*, 1990; Kühlbrandt *et al.*, 1994; Nogales *et al.*, 1998; Murata *et al.*, 2000; Gonen *et al.*, 2005; Holm *et al.*, 2006), where specimen cooling reduced the effect of radiation damage. One of these, the structure of bacteriorhodopsin (Henderson *et al.*, 1990) provided the first structure of a seven-helix membrane protein, and recent studies, particularly on aquaporins, are providing detailed insights into lipid–protein interactions (Reichow & Gonen, 2009). During the last few years, two different helical structures have allowed atomic models to be constructed from images of ice-embedded specimens (Miyazawa *et al.*, 2003; Yonekura, Maki-Yonekura & Namba, 2003) and the resolution of the best icosahedral structures has likewise improved dramatically to yield atomic models (*e.g.* Jiang *et al.*, 2008; Yu, Jin & Zhou, 2008; Zhang *et al.*, 2008; Chen *et al.*, 2009). Medium-resolution density distributions can often be interpreted in terms of the chemistry of the structure if a high-resolution model of one or more of the component pieces has already been obtained by X-ray, electron microscopy or NMR methods. As a result, the use of electron microscopy is becoming a powerful technique for which, in some cases, no alternative approach is possible. Numerous useful reviews (*e.g.* Amos *et al.*, 1982; Dubochet *et al.*, 1988; Baker *et al.*, 1999; van Heel *et al.*, 2000; Frank, 2002; Henderson, 2004; Chiu *et al.*, 2005) and books (Frank, 2006*b*; Glaeser *et al.*, 2007) have been written.

19.6.3. Physics of electron scattering and radiation damage

A schematic overview of scattering and imaging in the electron microscope is depicted in Fig. 19.6.3.1. The incident electron beam passes through the specimen and individual electrons are either unscattered or scattered by the atoms of the specimen. This scattering occurs either elastically, with no loss of energy and therefore no energy deposition in the specimen, or inelastically, with consequent energy loss by the scattered electron and accompanying energy deposition in the specimen, resulting in radiation damage. The electrons emerging from the specimen are then collected by the imaging optics, shown here for simplicity as a single lens, but in practice consisting of a complex system of five or six lenses with intermediate images being produced at successively higher magnification at different positions down the column. Finally, in the viewing area, either the electron-

Copyright © 2012 International Union of Crystallography

diffraction pattern or the image can be seen directly by eye on the phosphor screen, or detected by a TV or CCD camera, or recorded on photographic film.

In practice, the electron flux through the specimen is relatively low, so that only one electron at a time is in the column interacting with the specimen. This means that the unscattered and elastically scattered beams are in reality quantum-mechanical wavefronts, in which a wave function describes the probability distribution until the electron is actually recorded in the detector or on film. Where an inelastic event results in energy deposition and accompanying radiation damage in the specimen, the path of that electron, as well as its energy, wavelength and probability distribution, are slightly altered and this degrades the image.

19.6.3.1. Elastic and inelastic scattering

The coherent, elastically scattered electrons contain the high-resolution information describing the structure of the specimen. The amplitudes and phases of the scattered electron beams are directly related to the amplitudes and phases of the Fourier components of the atomic distribution in the specimen. When the scattered beams are recombined with the unscattered beam in the image, they create an interference pattern (the image) which, for thin specimens, is related approximately linearly to the density variations in the specimen. Information about the structure of the specimen can then be retrieved by digitization and computer-based image processing, as described in Section 19.6.5. The elastic scattering cross sections for electrons are not as simply related to the atomic composition as happens with X-rays. With X-ray diffraction, the scattering factors are simply proportional to the number of electrons in each atom, normally equal to the atomic number. Since elastically scattered electrons are in effect diffracted by the electrical potential inside atoms, the scattering factor for electrons depends not only on the nuclear charge but also on the size of the surrounding electron cloud, which screens the nuclear charge. As a result, electron scattering factors in the resolution range of interest in macromolecular structure determination (up to $\frac{1}{3}$ Å^{-1}) are very sensitive to the effective radius of the outer valency electrons and therefore depend sensitively on the chemistry of bonding. Although this is a fascinating field in itself with interesting work already carried out by the gas-phase electron-diffraction community (*e.g.* Hargittai & Hargittai, 1988), it is still an area where much work remains to be done. At present, it is probably adequate to think of the density obtained in macromolecular structure analysis by electron microscopy as roughly equivalent to the electron density obtained by X-ray diffraction but with the contribution from hydrogen atoms being somewhat greater relative to carbon, nitrogen and oxygen.

In-focus image

Figure 19.6.3.1
Schematic diagram showing the principle of image formation and diffraction in the transmission electron microscope. The incident beam, I_0, illuminates the specimen. Scattered and unscattered electrons are collected by the objective lens and focused back to form first an electron-diffraction pattern and then an image. For a 2D or 3D crystal, the electron-diffraction pattern would show a lattice of spots, each of whose intensity is a small fraction of that of the incident beam. In practice, an in-focus image has virtually no contrast, so images are recorded with the objective lens underfocused to take advantage of the out-of-focus phase-contrast mechanism. Higher electron doses than indicated can be used at lower resolution. The given dose of 5 e Å^{-2} applies for high-resolution (~4 Å) structural features.

Those electrons that are inelastically scattered lose energy to the specimen by a number of mechanisms. The energy-loss spectrum for a typical biological specimen is dominated by the large cross section for plasmon scattering in the energy range 20–30 eV with a continuum in the distribution which decreases up to higher energies. At discrete high energies, specific inner electrons in the *K* shell of carbon, nitrogen or oxygen can be ejected with corresponding peaks in the energy-loss spectrum appearing at 200–400 eV. Any of these inelastic interactions produces a deviation in the direction of the scattered electron and, as a result, the resolution of any information present in the energy-loss electron signal is reduced. Chromatic aberration in the objective lens results in these inelastic electrons contributing to the image only at relatively low resolution, around 15 Å (Isaacson *et al.*, 1974). Consequently, the inelastically scattered electrons are generally considered to contribute little, except noise, to the images. In the future, once electron cryo-microscopes with chromatic aberration correctors become available (expected by 2012), one may be able to obtain improved energy-loss images. Chromatic-aberration-corrected electron microscopes are already available for materials science (Kabius *et al.*, 2009).

19.6.3.2. Radiation damage

The most important consequence of inelastic scattering is the deposition of energy into the specimen. This is initially transferred to secondary electrons, which have an average energy (20 eV) that is five or ten times greater than the valence bond energies. These secondary electrons interact with other components of the specimen and produce numerous reactive chemical species, including free radicals. In ice-embedded samples, these would be predominantly highly reactive hydroxyl free radicals that arise from the frozen water molecules. In turn, these react with the embedded macromolecules and create a great variety of radiation products such as modified side chains, cleaved polypeptide backbones and a host of molecular fragments. From radiation-chemistry studies, it is known that thiol or disulfide groups react more quickly than aliphatic groups and that aromatic groups, including nucleic acid bases, are the most resistant (Burmeister, 2000; Weik *et al.*, 2000; Meents *et al.*, 2010). Nevertheless, the end effect of the inelastic scattering is the degradation of the specimen to produce a cascade of heterogeneous products, some of which resemble the starting structure more closely than others. Some of the secondary electrons also escape from the surface of the specimen, causing it to charge up during the exposure. As a rough rule, for 100 kV electrons the dose that can be used to produce an image in which the starting structure at high resolution is still recognizable is about 1 e Å^{-2} for organic or biological materials at room temperature, 5 e Å^{-2} for a specimen near liquid-nitrogen temperature ($-170\ ^\circ\text{C}$) and 10 e Å^{-2} for a specimen near liquid-helium temperature (4–8 K). However, individual experimenters will often exceed these doses if they wish to enhance the low-resolution information in the images, which is less sensitive to radiation damage. The effects of radiation damage owing to electron irradiation are essentially identical to those from X-ray or neutron irradiation for biological macromolecules except for the amount of energy deposition per useful coherent elastically scattered event (Henderson, 1995). For electrons scattered by biological structures at all electron energies of interest, the number of inelastic events exceeds the number of elastic events by a factor of three to four, so that 60 to 80 eV of energy is deposited for each elastically scattered electron. This limits the amount of information in an image of a single biological macromolecule. Consequently, the 3D atomic structure cannot be determined from a single molecule but requires the averaging of the information from a few thousand molecules in theory, and even more in practice (Henderson, 1995; Rosenthal & Henderson, 2003; Glaeser, 2008*b*; Cheng & Walz, 2009). Crystals used for X-ray or neutron diffraction contain many orders of magnitude more molecules.

It is possible to collect both the elastically and the inelastically scattered electrons simultaneously with an energy analyser and, if a fine electron beam is scanned over the specimen, then a scanning transmission electron micrograph displaying different properties of the specimen can be obtained (*e.g.* Tichelaar *et al.*, 1980; Crewe, 1983; Muller *et al.*, 2008). Alternatively, conventional transmission electron microscopes to which an energy filter has been added can be used to select out a certain energy band of the electrons from the image (*e.g.* Yonekura *et al.*, 2006; Maki-Yonekura & Yonekura, 2008). Both these types of microscopy can contribute in other ways to the knowledge of structure, but in this article we concentrate on high-voltage phase-contrast electron microscopy of unstained macromolecules most often embedded in ice, because this is the method of widest impact in structural biology.

19.6.3.3. *Required properties of the illuminating electron beam*

The important properties of the image in terms of defocus, astigmatism, and the presence and effect of amplitude or phase contrast are discussed in Section 19.6.5. Microscopes with field emission guns (FEGs) produce the best-quality incident electron beams. This is because the electrons from a FEG are emitted from a very small volume at the tip, which is the apparent source size. Once these electrons have been collected by the condenser lens and used to produce the illuminating beam, that beam of electrons is then very parallel (divergence of $\sim 10^{-2}$ mrad) and therefore spatially coherent. Similarly, because the emitting tip of a FEG is not heated as much as a conventional thermionic tungsten source, the thermal-energy spread of the electrons is relatively small (0.5 to 1.0 eV) and the illuminating beam is closer to being monochromatic. Electron beams can also be produced by a normal heated tungsten source, which gives a less parallel beam with a larger energy spread, but is nevertheless adequate for cryoTEM if the highest resolution images are not required.

19.6.4. Three-dimensional electron cryomicroscopy of macromolecules

The determination of 3D structures by cryoTEM methods follows a common scheme for all macromolecules (Fig. 19.6.4.1). A more detailed discussion of the individual steps as applied to different classes of macromolecules appears in subsequent sections. Briefly, each specimen must be prepared in a relatively homogeneous aqueous form (1D or 2D crystals or a suspension of single particles in a limited number of states) at relatively high concentration, rapidly frozen (vitrified) as a thin film, transferred into the electron microscope and imaged using low-dose selection and focusing procedures. The resulting images are more frequently being recorded using an electronic detector. Alternatively, if recorded on film, they must then be digitized. Digitized images are then processed using computer programs that allow different views of the specimen to be combined into a 3D reconstruction that can be interpreted in terms of other available structural, biochemical and molecular data.

19.6.4.1. *Overview of conceptual steps*

Radiation damage by the illuminating electron beam generally allows only one good picture (micrograph) to be obtained from

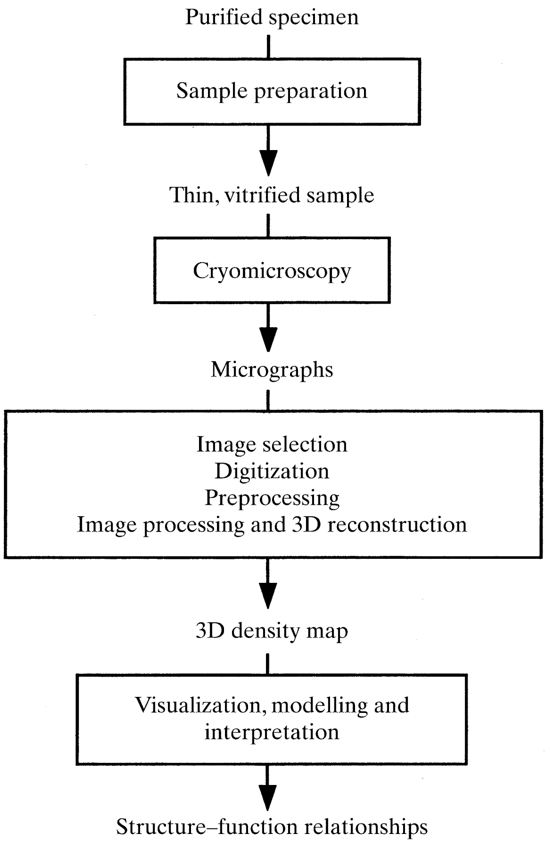

Figure 19.6.4.1
Flow diagram showing common procedures involved in cryoTEM from sample preparation to map interpretation.

each molecule or macromolecular assembly. In this micrograph, the signal-to-noise ratio of the 2D projection image is normally too small to determine the projected structure accurately. This implies firstly that it is necessary to average many images of different molecules taken from essentially the same viewpoint to increase the signal-to-noise ratio, and secondly that many of these averaged projections, taken from different directions, must be combined to build up the information necessary to determine the 3D structure of the molecule. Thus, the two key concepts are: (1) averaging to a greater or lesser extent depending on resolution, particle size and symmetry to increase the signal-to-noise ratio; and (2) the combination of different projections to build a 3D map of the structure.

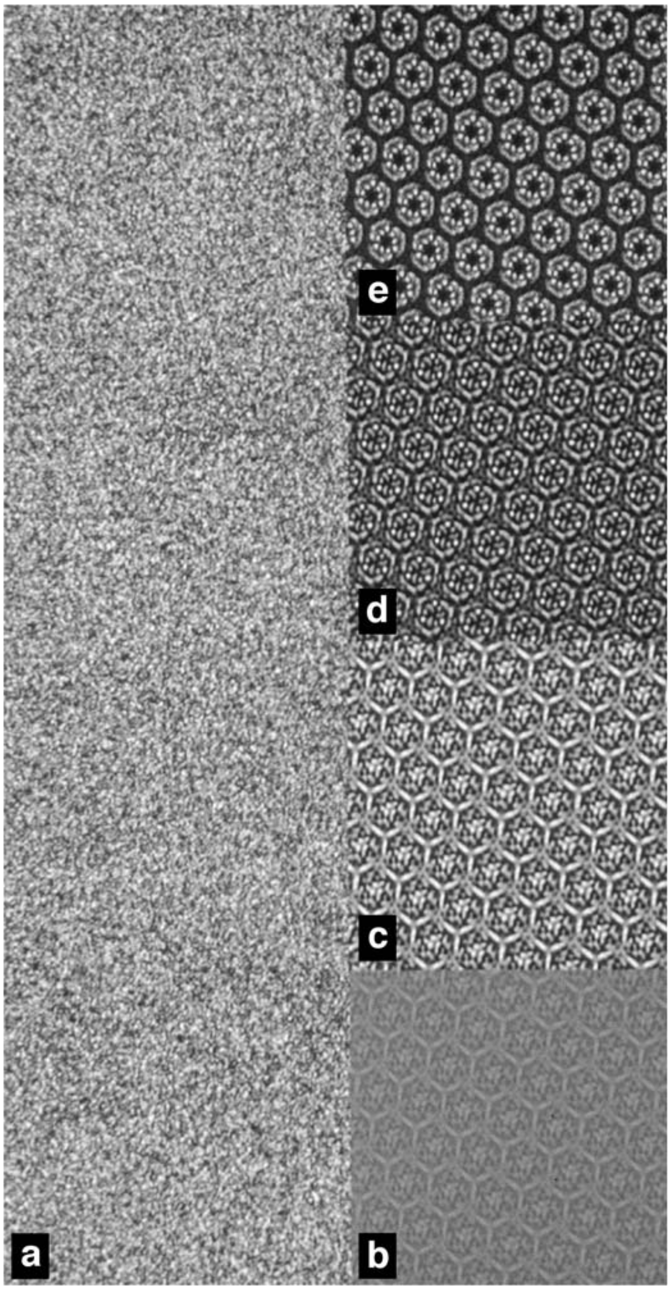

Figure 19.6.4.2
A display of the results at different stages of image processing of a digitized micrograph of a 2D crystal of bacteriorhodopsin. The left panel (*a*) shows an area of the raw digitized micrograph in which only electron noise is visible. The lower right panel (*b*) shows the results of the averaging of unit cells from the whole picture by unbending in real space and filtering in reciprocal space. The scale of the density in (*b*) is the same as that in the original micrograph, showing that the signal is very much weaker than the noise. Panel (*c*) shows the same density as in (*b*) but with contrast increased tenfold to show that the signal in the original picture is approximately 10× below the noise level. Panel (*d*) shows the density after correction for the contrast-transfer function (CTF) due in this case to a defocus of 6000 Å. Panel (*e*) shows the density after further threefold crystallographic averaging (the space group is *p*3 with a cell dimension of 62.5 Å) and replacement of image amplitudes by electron-diffraction amplitudes. Panel (*e*) therefore shows an almost perfect atomic resolution image of the projected structure of bacteriorhodopsin. The trimeric rings of molecules are centred on the crystallographic threefold axes and the internal structure shows α-helical segments in the protein.

In addition, there are various technical corrections that must be made to the image data to allow an unbiased model of the structure to be obtained. These include correction for the phase contrast-transfer function (CTF) of the microscope and, at high resolution, for the effects of beam tilt. For crystals, it is also possible to combine electron-diffraction amplitudes with image phases to produce a more accurate structure (Unwin & Henderson, 1975), or to use new electron-diffraction data to improve a previous model (Gonen *et al.*, 2005), and in general to correct for loss of high-resolution contrast for any reason by ‘sharpening’ the data by application of a negative temperature factor (Havelka *et al.*, 1995; Rosenthal & Henderson, 2003; Fernandez *et al.*, 2008).

The idea of increasing the signal-to-noise ratio in electron images of unstained biological macromolecules by averaging was discussed in 1971 (Glaeser, 1971) and demonstrated in 1975 (Henderson & Unwin, 1975; Unwin & Henderson, 1975), though earlier work on stained specimens had shown the value of averaging to increase the signal-to-noise ratio (Klug & DeRosier, 1966). The improvement obtained, as in all repeated measurements, gives a factor of $N^{1/2}$ improvement in signal-to-noise ratio, where N is the number of times the measurement is made. The effect of averaging to produce an improvement in signal-to-noise ratio is seen most clearly in the processing of images from 2D crystals. For example, Fig. 19.6.4.2 shows the results of applying a sequence of corrections, beginning with averaging, to 2D crystals of bacteriorhodopsin in 2D space group *p*3. The panels show: (*a*) raw, digitized image, (*b*, *c*) 2D averaging, (*d*) correction for the microscope CTF, and (*e*) threefold crystallographic symmetry averaging of the phases and combination with electron-diffraction amplitudes. At each stage, the projected picture of the molecules gets clearer. The final stage results in a virtually noise-free projected structure for the molecule at near-atomic (3 Å) resolution.

The earliest successful application of the idea of combining projections to reconstruct the 3D structure of a biological assembly was made by DeRosier & Klug (1968). The idea is that each 2D projection corresponds after Fourier transformation to a central section of the 3D transform of the assembly. If enough independent projections are obtained, then the 3D transform will have been fully sampled and the structure can then be obtained by back-transformation of the averaged, interpolated and smoothed 3D transform. This procedure is shown schematically for a 3D object in the shape of a duck, which represents the molecule whose structure is being determined (Fig. 19.6.4.3).

In practice, the implementation of these concepts has been carried out in a variety of ways, since the experimental strategy and type of computer analysis used depends on the type of specimen, especially the molecular mass of the individual molecule, its symmetry and whether or not it assembles into an aggregate with 1D, 2D or 3D periodic order.

Figure 19.6.4.3
Schematic diagram to illustrate the principle of 3D reconstruction. Each 2D projected image, as recorded on the micrograph and after CTF correction, represents a section through the 3D Fourier transform. This is called the projection theorem. After accumulation of enough information from enough different views, a 3D map of the structure can be calculated by Fourier inversion.

19.6.4.2. Classification of macromolecules

The symmetry of a macromolecule or supramolecular complex is the primary determinant of how specimen preparation, microscopy and 3D image reconstruction are performed (Sections 19.6.4.3, 19.6.4.4 and 19.6.5). The classification of molecules according to their level of periodic order and symmetry (Table 19.6.4.1) provides a logical and convenient way to consider the means by which specimens are studied in 3D by microscopy.

Each type of specimen offers a unique set of challenges in obtaining 3D structural information at the highest possible resolution. The best resolutions achieved by 3D EM methods to date, at about 2–4 Å, have been obtained with several thin 2D crystals, in large part due to their excellent order, with helical arrays and icosahedral single particles now crossing the 4 Å barrier (Cheng & Walz, 2009).

With the exception of true 3D crystals, which must be sectioned to make them thin enough to study by transmission electron microscopy, the resolution obtained with biological specimens is generally dictated by the preservation of periodic order, and the symmetry and complexity of the object. Hence, studies for example of 2D crystals of the aquaporin membrane channel (Gonen *et al.*, 2005), helical acetylcholine receptor tubes (Miyazawa *et al.*, 2003) and bacterial flagella (Yonekura, Maki-Yonekura & Namba, 2003), three icosahedral virus capsids (Yu, Jin & Zhou, 2008; Zhang *et al.*, 2008; Chen *et al.*, 2009), the 70S *E. coli* ribosome (LeBarron *et al.*, 2008), and HIV trimers obtained by sub-tomogram averaging (Liu, Bartesaghi *et al.*, 2008), have yielded 3D density maps at resolutions of 1.9, 4.0, 4.0, 4.0, 3.8, 3.8, 6.7 and 19 Å, respectively.

If high resolution were the sole objective of EM, it would be necessary, given the capabilities of existing technology, to try to form well ordered 2D crystals, helical assemblies or icosahedral particles of each macromolecule of interest. Indeed, a number of different crystallization techniques have been devised (*e.g.* Yoshimura *et al.*, 1990; Kornberg & Darst, 1991; Jap *et al.*, 1992; Kubalek *et al.*, 1994; Hasler *et al.*, 1998; Wilson-Kubalek *et al.*, 1998; Dang *et al.*, 2005; Schmidt-Krey, 2007) and some of these have yielded new structural information about otherwise recalcitrant molecules like RNA polymerase (Polyakov *et al.*, 1998). However, despite the obvious technological advantages of having a molecule present in a highly ordered form, most macromolecules function not as highly ordered crystals or helices but instead as single particles (*e.g.* many enzymes) or, more likely, in concert with other macromolecules as occurs in supramolecular assemblies. Also, crystallization tends to constrain the number of conformational states a molecule can adopt and the crystal conformation might not be functionally relevant. Hence, though resolution may be restricted to less than that realized in the bulk of current X-ray crystallographic studies, cryoTEM methods provide a powerful means to study molecules that resist crystallization in 1D, 2D or 3D. These methods allow one to explore the dynamic events, different conformational states (as induced, for example, by altering the microenvironment of the specimen) and macromolecular interactions that are the key to understanding how each macromolecule functions.

19.6.4.3. Specimen preparation

The goal in preparing specimens for cryoTEM is to keep the biological sample in its native state as closely as possible in order to preserve the structure to atomic or near-atomic resolution in the microscope and during microscopy. The methods by which numerous types of macromolecules and macromolecular complexes have been prepared for cryoTEM studies are now well established (Adrian *et al.*, 1984; Bellare *et al.*, 1988; Dubochet *et al.*, 1988; Grassucci *et al.*, 2007). Most such methods involve cooling samples at a rate fast enough to permit vitrification (to a solid glass-like state) rather than crystallization of the bulk water. Noncrystalline biological macromolecules are typically vitrified by applying a small (often <5 µl) aliquot of a purified ~0.2–5 mg ml^{-1} suspension of sample to an EM grid coated with a carbon or holey carbon support film. The grid, secured with a pair of forceps and suspended over a container of ethane or propane cryogen slush (maintained near its freezing point by a reservoir of liquid nitrogen), is blotted nearly dry with a piece of filter paper. The grid is then plunged into the cryogen, and the sample, if thin

Table 19.6.4.1

Classification of macromolecules according to periodic order and symmetry

Periodic order	Type	Symmetry	Example macromolecule/complex	Representative reference
0D	Point group	C_1	70S ribosome (bacterial)	Villa *et al.* (2009)

† The symmetry of a helical structure is defined by an n_m screw axis, which combines a rotation of $2\pi/n$ radians about an axis followed by a translation of m/n of the repeat distance. Because many helical structures are polymorphic, a different n_m symmetry is needed to specify each polymorph. This designation can be confusing: for example, for tobacco mosaic virus $n_m = 16.333_{0.333}$, because the helical translational repeat consists of 49 subunits in three turns of the basic helix.

enough (~0.2 µm or less), is vitrified in millisecond or shorter time periods (Mayer & Astl, 1992; Berriman & Unwin, 1994; White *et al.*, 1998; Kasas *et al.*, 2003).

The ability to freeze samples on a timescale of milliseconds affords cryoTEM one of its unique and perhaps still under-utilized advantages: capturing and visualizing dynamic structural events that occur over time periods of a few milliseconds or longer. Several devices that allow samples to be perturbed in a variety of ways as they are plunged into a cryogen have been described (*e.g.* Subramaniam *et al.*, 1993; Berriman & Unwin, 1994; Siegel *et al.*, 1994; Trachtenberg, 1998; White *et al.*, 1998, 2003; Shaikh *et al.*, 2009), and there are now commercially available freeze-plungers (*e.g.* Iancu *et al.*, 2006; Melanson, 2009). Examples of the use of such devices include spraying acetylcholine onto its receptor to cause the receptor channel to open (Unwin, 1995), lowering the pH of an enveloped virus sample to initiate early events of viral fusion (Fuller *et al.*, 1995), inducing a temperature jump with a flash-tube system to study phase transitions in liposomes (Siegel & Epand, 1997), or mixing myosin S1 fragments with F-actin to examine the geometry of the cross-bridge powerstroke in muscle (Walker *et al.*, 1999).

Crystalline (2D) samples can fortunately often be prepared for cryoTEM by means of simpler procedures, and vitrification of the bulk water is not always essential to achieve success (Cyrklaff & Kühlbrandt, 1994). Such specimens may be applied to the carbon film on an EM grid by normal adhesion methods, washed with 1–2% solutions of solutes like glucose, trehalose or tannic acid, blotted gently with filter paper to remove excess solution, air dried, loaded into a cold holder, inserted into the microscope, and, finally, cooled to liquid-nitrogen temperature.

19.6.4.4. Microscopy

Once the vitrified specimen is inserted into the microscope and sufficient time is allowed (~15 min) for the specimen stage to stabilize to minimize drift and vibration, microscopy is performed to generate a set of images that, with suitable processing procedures, can later be used to produce a reliable 3D reconstruction of the specimen at the highest possible resolution. To achieve this goal, imaging must be performed at an electron dose that minimizes beam-induced radiation damage to the specimen, with the objective lens of the microscope defocused to enhance phase contrast from the weakly scattering, unstained biological specimen, and under conditions that keep the specimen below the devitrification temperature (~−140 °C) and minimize its contamination.

The microscopist locates specimen areas suitable for image recording by searching the EM grid at very low magnification ($\leq 3000\times$) to keep the irradiation level quite low (<0.05 e Å^{-2} s^{-1}) while assessing sample quality. In microscopes operated at 200 keV or higher, where image contrast is very weak, it is helpful to perform the search procedure with the assistance of a CCD camera or a video-rate TV-intensified camera system. Indeed, these are now much more sensitive than looking at a phosphor screen by eye. For some specimens, like thin 2D crystals, searching is conveniently performed while viewing the low-magnification high-contrast image produced by using the diffraction lens to give a slightly defocused electron-diffraction pattern. Electronic detectors also have automatic histogram expansion settings that allow amplification of small contrast differences on a display monitor. These become more-or-less essential when using high-voltage (300 keV) microscopes.

After a desired specimen area is identified, the microscope is switched to high-magnification mode for focusing and astigmatism correction. These adjustments are typically performed in a region ~2–5 µm away from the chosen area at the same or higher magnification than that used for final image recording. The choice of magnification, defocus level, accelerating voltage, beam coherence, electron dose and other operating conditions is dictated by several factors. The most significant ones are the size of the particle or crystal unit cell being studied, the anticipated resolution of the images and the requirements of the image processing needed to compute a 3D reconstruction to the desired resolution. For most specimens at required resolutions from 3 to 30 Å, images are typically recorded at 25 000–50 000× magnification with an electron dose of between 5 and 20 e Å^{-2}. These conditions yield micrographs of sufficient optical density (film OD 0.2–1.5) or dynamic range (CCD detector) and image resolution for subsequent image-processing steps (Section 19.6.5). All modern EMs provide some mode of low-dose operation for imaging beam-sensitive, vitrified biological specimens.

The intrinsic low contrast of unstained specimens makes it impossible to observe and focus on specimen details directly as is routine with stained or metal-shadowed specimens. Focusing, aimed to enhance phase contrast in the recorded images while minimizing beam damage to the desired area, is achieved by judicious defocusing on a region that is adjacent to the region to be photographed and preferably situated on the microscope tilt axis. The appropriate focus level is set by adjusting the appearance of either the Fresnel fringes that occur at the edges of holes in the carbon film or the 'phase granularity' from the carbon support film.

Unfortunately, electron images do not give a direct rendering of the specimen density distribution. The relationship between image and specimen is described by the CTF which is characteristic of the particular microscope used, the specimen and the conditions of imaging. The microscope CTF arises from the objective-lens focal setting and from the spherical aberration present in all electromagnetic lenses, and varies with the defocus and accelerating voltage according to equation (19.6.4.1), an expression that includes both phase and amplitude contrast components. First, however, it is useful to consider briefly the essentials of amplitude contrast and phase contrast, two concepts carried over from optical microscopy. Amplitude contrast refers to the nature of the contrast in an image of an object that absorbs the incident illumination or scatters it in any other way so that a portion of it is lost. As a result, the image appears darker where greater absorption occurs. Phase contrast is required if an object is transparent (*i.e.* it is a pure phase object) and does not absorb but only scatters the incident illumination. Biological specimens for cryoTEM are almost pure phase objects and the scattering is relatively weak. Hence, the simple theory of image formation by a weak phase object applies (Reimer & Kohl, 2008; Spence, 2009). An exactly in-focus image of a phase object has no contrast variation since all the scattered illumination is focused back to equivalent points in the image of the object from which it was scattered. In optical microscopy, the use of a quarter wave plate can retard the phase of the direct unscattered beam, so that an in-focus image of a phase object has very high 'Zernicke' phase contrast (Glaeser, 2008*a*). However, there is as yet no simple quarter wave plate for electrons, so instead phase contrast is created by introducing phase shifts into the diffracted beams by adjustment of the excitation of the objective lens so that the image is slightly defocused. In addition, since all matter is composed of atoms and the electric potential inside each atom is very high near the nucleus, even the electron-scattering behaviour of the light atoms found in biological molecules deviates from that of a weak phase object. For a more in-depth discussion of this the reader should refer to Reimer & Kohl (2008) or Spence (2009). In practice, the proportion of 'amplitude' contrast is about 7% at 100 kV, 5% at 200 kV and 4% at 300 kV for low-dose images of protein molecules embedded in ice.

The overall dependence of the CTF on resolution, wavelength, defocus and spherical aberration is

$$\mathrm{CTF}(\nu) = -\Big\{\big(1 - F_{\rm amp}^2\big)^{1/2}\sin[\chi(\nu)] + F_{\rm amp}\cos[\chi(\nu)]\Big\}, \tag{19.6.4.1}$$

where $\chi(\nu) = \pi\lambda\nu^2(\Delta f - 0.5C_s\lambda^2\nu^2)$, ν is the spatial frequency (in Å^{-1}), $F_{\rm amp}$ is the fraction of amplitude contrast, λ is the electron wavelength (in Å), where $\lambda = 12.3/(V + 0.000000978V^2)^{1/2}$ (= 0.037, 0.025 and 0.020 Å for 100, 200 and 300 keV electrons, respectively), V is the voltage (in volts), Δf is the underfocus (in Å) and C_s is the spherical aberration of the objective lens of the microscope (in Å).

In addition, the CTF is attenuated by an envelope or damping function that depends upon the spatial and temporal coherence of the beam, specimen drift and other factors (Erickson & Klug, 1971; Wade & Frank, 1977; Wade, 1992). Representative CTFs for different amounts of defocus on a conventional tungsten and a FEG microscope are illustrated in Fig. 19.6.4.4. For a particular defocus setting of the objective lens, phase contrast in the electron image is positive and maximal only at a few specific spatial frequencies. Contrast is either lower than maximal, completely absent or it is opposite (inverted or reversed) from that at other frequencies. Hence, as the objective lens is focused, the electron microscopist selectively accentuates image details of a particular size.

Images are typically recorded 0.8–3.0 µm underfocus to enhance specimen features in the 20–40 Å size range and thereby facilitate phase-origin and specimen-orientation search procedures carried out in the image-processing steps (Section 19.6.5). However, this level of underfocus also enhances contrast in lower-resolution maps, which may help in interpretation. To obtain results at sub-nanometre (<10 Å) resolution, it is normal to record, process and combine data from several micrographs that span a range of defocus levels (*e.g.* Unwin & Henderson, 1975; Böttcher *et al.*, 1997). This strategy assures good information transfer at all spatial frequencies up to the limiting resolution but requires careful compensation for the effects of the microscope CTF during image processing. Also, the recording of image focal pairs or focal series from a given specimen area can be beneficial in determining origin and orientation parameters for processing of images of single particles (*e.g.* Cheng *et al.*, 1992; Conway & Steven, 1999).

Most high-resolution cryoTEM studies are now performed with microscopes operated at 200 keV or higher and with FEG electron sources (*e.g.* Zemlin, 1992; Zhou & Chiu, 1993; Ludtke *et al.*, 2008; Yu, Jin & Zhou, 2008; Zhang *et al.*, 2008). The high coherence of a FEG source ensures that phase contrast in the images remains strong out to high spatial frequencies (>1/3.5 Å^{-1}) even for highly defocused images. The use of higher voltages provides potentially higher resolution (greater depth of field – *i.e.* less curvature of the Ewald sphere – owing to the smaller electron-beam wavelength), better beam penetration (less multiple scattering), reduced problems with specimen charging that plague microscopy of unstained or uncoated vitrified specimens (Brink *et al.*, 1998) and reduced phase shifts associated with beam tilt.

Images are recorded on photographic film or on an electronic camera with either flood-beam or spot-scan procedures. Film, with its advantages of low cost, large field of view and high resolution (~10 µm), has remained the primary image-recording medium for most high-resolution cryoTEM applications, despite disadvantages of high background fog and need for chemical development and digitization. Electronic (usually phosphor/fibre optic/CCD) cameras provide image data directly in digital form and with very low background noise, but suffer from higher cost, limited field of view, limited spatial resolution caused by poor point-spread characteristics and a fixed pixel size (typically between 14 and 24 µm). They are useful, for example, for precise focusing and adjustment of astigmatism (*e.g.* Krivanek & Mooney, 1993; Sherman *et al.*, 1996) and are increasingly used to acquire image data for 3D reconstruction studies (*e.g.* Booth *et al.*, 2004; Sander *et al.*, 2005; Booth *et al.*, 2006; Chen *et al.*, 2008). There is a useful comparison of the MTF and DQE at different spatial frequencies between film and several electronic detectors (McMullan, Chen *et al.*, 2009). In summary, at present, all image recording is better at low (*e.g.* 120 kV) voltage with little to choose between different recording media, but film, in 2009, is still best at 300 keV.

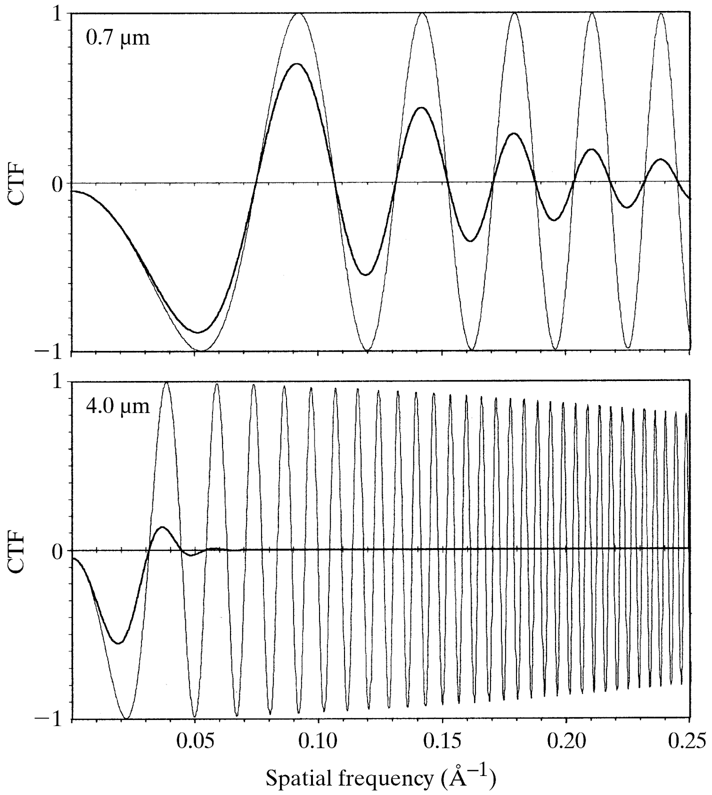

Figure 19.6.4.4
Representative plots of the microscope CTF as a function of spatial frequency, for two different defocus settings (0.7 and 4.0 µm underfocus) and for a field-emission (light curve) or tungsten (dark curve) electron source. All plots correspond to electron images formed in an electron microscope operated at 200 kV with objective-lens aberration coefficients $C_s = C_c = 2.0$ mm and assuming amplitude contrast of 4.8% (Toyoshima *et al.*, 1993). The spatial coherence, which is related to the electron source size and expressed as β, the half-angle of illumination, for tungsten and FEG electron sources was fixed at 0.3 and 0.015 mrad, respectively. Likewise, the temporal coherence (expressed as ΔE, the energy spread) was fixed at 1.6 and 0.5 eV for tungsten and FEG sources. The combined effects of the poorer spatial and temporal coherence of the tungsten source leads to a significant dampening, and hence loss of contrast, of the CTF at progressively higher resolutions compared with that observed in FEG-equipped microscopes. The greater number of contrast reversals with higher defocus arises because of the greater out-of-focus phase shifts.

For studies in which specimens must be tilted to collect 3D data, such as with 2D crystals, single particles that adopt preferred orientations on the EM grid or specimens requiring tomography, microscopy is performed in essentially the same way as described above. However, the limited tilt range (±60–70°) of most microscope goniometers can lead to non-isotropic resolution in the 3D reconstructions (the 'missing wedge' or missing cone' problem), and tilting generates a constantly varying defocus across the field of view in a direction normal to the tilt axis. The effects caused by this varying defocus level must be corrected in high-resolution applications (Henderson *et al.*, 1990).

19.6.4.5. Selection and preprocessing of digitized images

Before any image analysis or classification of the molecular images can be done, a certain amount of preliminary checking and normalization is required to ensure there is a reasonable chance that a homogeneous population of molecular images has been obtained. First, good-quality micrographs are selected in which the electron exposure is correct, there is negligible image drift or blurring, and there is minimal astigmatism and a reasonable amount of defocus to produce good phase contrast. This is usually done by visual examination and optical diffraction or examination of the computed diffraction pattern.

Once the best micrographs have been chosen, if they are on film they must be scanned and digitized on a suitable densitometer. The sizes of the steps between digitization of optical density, and the size of the sample aperture over which the optical density is averaged by the densitometer, must be sufficiently small to sample the detail present in the image at fine enough intervals (DeRosier & Moore, 1970). Normally, a circular (or square) sample aperture of diameter (or length of side) equal to the step between digitization is used. This avoids digitizing overlapping points, without missing any of the information recorded in the image. The size of the sample aperture and digitization step depends on the magnification selected and the resolution required. A value of one-quarter to one-third of the required limit of resolution (measured in μm on the emulsion) is normally ideal, since it avoids having too many data points (and therefore wasting computer resources) without losing anything during the measurement procedure. For a 40 000× image, on which a resolution of 10 Å at the specimen is required, a step size of 10 μm [= $(1/4)(10\ \text{Å} \times 40\,000/10\,000\ \text{Å}\ \mu\text{m}^{-1})$] would be suitable.

The best area of an image of a helical or 2D crystal specimen can then be boxed off using a soft-edged mask. For images of single particles, a small, often circular region surrounding each particle is selected to create a stack of many individual particles. In the later steps of image processing, because the orientation and position of each particle are refined by comparing the amplitudes and phases of their Fourier components, it is important to remove spurious features around the edge of each particle and to make sure the different particle images are on the same scale. This is normally done by masking off a circular area centred on each particle and floating the density so that the average around the perimeter becomes zero (DeRosier & Moore, 1970). The edge of the mask is apodized by applying a soft cosine bell shape to the original densities so they taper towards the background level. Finally, to compensate for variations in the exposure due to ice thickness or electron dose, most people normalize the stack of individual particle images so that the mean density and mean density variation over the field of view are set to the same values for all particles (Carrascosa & Steven, 1978).

Once some good particles or crystalline areas for 1D or 2D crystals have been selected, digitized and masked and their intensity values have been normalized, true image processing can begin.

19.6.5. Image processing and 3D reconstruction

Although the general concepts of signal averaging, together with combining different views to reconstruct the 3D structure, are common to the different computer-based procedures that have been implemented, it is important to emphasize one or two preliminary points. First, a homogeneous set of particles must be selected for inclusion in the 3D reconstruction. This selection may be made by eye to eliminate obviously damaged particles or impurities, or by the use of multivariate statistical analysis (van Heel & Frank, 1981) or some other classification scheme, such as local cross-correlation (Roseman, 2003). This allows a subset of the particle images to be used to determine the structure of a better-defined entity. All image-processing procedures require the determination of the same parameters that are needed to specify unambiguously how to combine the information from each micrograph or particle. These parameters are: the magnification, defocus, astigmatism and, at high resolution, the beam tilt for each micrograph; the electron wavelength used (*i.e.* accelerating voltage of the microscope); the spherical aberration coefficient, C_s, of the objective lens; and the orientation and phase origin for each particle or unit cell of the 1D, 2D or 3D crystal. There are 13 parameters for each particle, eight of which may be common to each micrograph and two or three (C_s, accelerating voltage, magnification) to each microscope. The different general approaches that have been used in practice to determine the 3D structure of different classes of macromolecular assemblies from one or more electron micrographs are listed in Table 19.6.5.1.

The precise way in which each general approach codes and determines the particle or unit-cell parameters varies greatly and is not described in detail. Much of the computer software used in image-reconstruction studies is relatively specialized compared with that used in the more mature field of macromolecular X-ray crystallography. In part, this may be attributed to the large diversity of specimen types amenable to cryoTEM and reconstruction methods. As a consequence, image-reconstruction software is still evolving quite rapidly, and references to software packages cited in Table 19.6.5.1 are likely to become quickly outdated. Extensive discussion of algorithms and software packages may be found in several special issues of *Journal of Structural Biology* [Vol. 116, pp. 1–249 (1996); Vol. 120, pp. 207–396 (1997); Vol. 125, pp. 95–254 (1999); Vol. 133, pp. 89–266 (2001); Vol. 138, pp. 1–155 (2002); Vol. 144, pp. 1–252 (2003); Vol. 145, pp. 1–180 (2004); Vol. 157, pp. 1–296 (2007); Vol. 160, pp. 263-404 (2007); and Vol. 161, pp. 219–480 (2008)]. Tomography is the topic of Volumes 120, 138 and 161, single-particle cryoTEM is covered in Volume 133, particle-picking algorithms are covered in Volume 145 and electron crystallography of membrane proteins is covered in Volume 160.

In practice, attempts to determine or refine some parameters may be affected by the inability to determine accurately one of the other parameters. The solution of the structure is therefore an iterative procedure in which reliable knowledge of the parameters that describe each image is gradually built up to produce a more and more accurate structure until no more information can be squeezed out of the micrographs. At this point, if any of the origins or orientations are wrongly assigned, there will be a loss of detail and a decrease in signal-to-noise ratio in the map. If a better-determined or higher-resolution structure is required, it would then be necessary to record images on a better microscope or to prepare new specimens and record better pictures.

The reliability and resolution of the final reconstruction can be measured using a variety of indices. For example, the DPR (Frank *et al.*, 1981), the FSC (van Heel, 1987*b*) and the Q factor (van Heel & Hollenberg, 1980) are three such measures. The DPR is the mean phase difference, as a function of resolution, between the structure factors from two independent reconstructions, often calculated by splitting the image data into two halves. The FSC is a similar calculation of the mean correlation

Table 19.6.5.1
Methods of three-dimensional image reconstruction

Structure type (symmetry)	Method	Reference(s) to technical/theoretical details
Asymmetric (point group C_1)	Random conical tilt	Radermacher *et al.* (1987); Radermacher (1988)

† Electron tomography is the subject of several recent reviews (Jonic *et al.*, 2008; McEwen *et al.*, 2008; Morris & Jensen, 2008; Steven & Baumeister, 2008; Bárcena & Koster, 2009; Bartesaghi & Subramaniam, 2009; Hoenger & McIntosh, 2009; Leis *et al.*, 2009; Li & Jensen, 2009), three special issues of *Journal of Structural Biology* [Vol. 120, pp. 207–395 (1997); Vol. 138, pp. 1–155 (2002); and Vol. 161, pp. 219–480 (2008)] and a book edited by Frank (2006*a*).

coefficient between the complex structure factors of the two halves of the data as a function of resolution. The Q factor is the mean ratio of the vector sum of the individual structure factors from each image divided by the sum of their moduli, again calculated as a function of resolution. Perfectly accurate measurements would have values of the DPR, FSC and Q factor of 0°, 1.0 and 1.0, respectively, whereas random data containing no information would have values of 90°, 0.0 and 0.0. The spectral signal-to-noise ratio (SSNR) criterion has been advocated as the best of all (Unser *et al.*, 1989): it effectively measures, as a function of resolution, the overall signal-to-noise ratio (squared) of the whole of the image data. It is calculated by taking into consideration how well all the contributing image data agree internally.

An example of a strategy for determination of the 3D structure of a new and unknown molecule without any symmetry and which does not crystallize might be as follows:

1. Record a single-axis tilt series of particles embedded in negative stain, with a tilt range from −60° to +60°.
2. Calculate 3D structures for each of several different particles using an *R*-weighted back-projection algorithm (Radermacher, 1992).
3. Average 3D data for several particles in real or reciprocal space to get a reasonably good 3D model of the stain-excluding region of the particle.
4. Record a number of micrographs of the particles embedded in vitreous ice.
5. Use the 3D negative-stain model obtained in (3) with inverted contrast to determine the rough alignment parameters of the particle in the ice images.
6. Calculate a preliminary 3D model of the average ice-embedded structure.
7. Use the preliminary 3D model to determine more accurate alignment parameters for the particles in the ice images.
8. Calculate a better 3D model.
9. Determine defocus and astigmatism for each micrograph to allow CTF calculation and correct 3D model so that it represents the structure at high resolution.
10. Keep adding images at different defocus levels to get an accurate structure at as high a resolution as possible.
11. Correct the final structure for resolution-dependent contrast loss and apply a damping factor dependent on signal-to-noise ratio (Rosenthal & Henderson, 2003).

For large single particles with no symmetry, particles with higher symmetry or crystalline arrays, it should be possible to omit the negative-staining steps (1)–(3) and go straight to alignment of particle images from ice embedding, because the particle or crystal tilt angles can be determined internally from comparison of phases along common lines in reciprocal space or from the lattice or helix parameters from a 2D or 1D crystal.

The following discussion briefly outlines for a few specific classes of macromolecule the general strategy for carrying out image processing and 3D reconstruction.

19.6.5.1. 2D crystals

For 2D crystals, the general 3D reconstruction approach consists of the following steps. First, a series of micrographs of single 2D crystals are recorded at different tilt angles, with random azimuthal orientations. Each crystal is then unbent using cross-correlation techniques to identify the precise position of each unit cell (Henderson *et al.*, 1986), and amplitudes and phases of the Fourier components of the average of that particular view of the structure are obtained for the transform of the unbent crystal. The reference image used in the cross-correlation calculation can either be a part of the whole image masked off after a preliminary round of averaging by reciprocal-space filtering of the regions surrounding the diffraction spots in the transform, or it can be a reference image calculated from a previously determined 3D model. The amplitudes and phases from each image are then corrected for the CTF and beam tilt (Henderson *et al.*, 1986, 1990; Kunji *et al.*, 2000) and merged with data from many other crystals by scaling and origin refinement, taking into account the proper symmetry of the 2D space group of the crystal (Landsberg & Hankamer, 2007). Finally, the whole data set is fitted by least squares to constrained amplitudes and phases along the lattice lines (Agard, 1983) prior to calculating a 3D map of the structure. The initial determination of the 2D space group can be carried out by a statistical test of the phase relationships in one or two images of untilted specimens (Valpuesta *et al.*, 1994). The absolute hand of the structure is automatically correct since the 3D structure is calculated from images whose tilt axes and tilt angles are known. Nevertheless, care must be taken not to make any of a number of trivial mistakes that would invert the hand. Recent efforts have been devoted to create a user-friendly interface for image processing of 2D crystals (Gipson, Zeng & Stahlberg, 2007; Gipson, Zeng, Zhang & Stahlberg, 2007; Zeng *et al.*, 2007). The entire topic of processing images of 2D crystals and evaluating the data has been the subject of several publications and reviews (*e.g.* Yeager *et al.*, 1999; Unger, 2000; Renault *et al.*, 2006; Hite *et al.*, 2007; Kovacs *et al.*, 2008).

19.6.5.2. Helical particles

The basic steps involved in processing and 3D reconstruction of helical specimens include the following. First, record a series of micrographs of vitrified particles suspended over holes in a perforated carbon support film. The micrographs are digitized and Fourier transformed to determine image quality (astigmatism, drift, defocus, presence and quality of layer lines, *etc.*). Individual particle images are boxed, floated and apodized within a rectangular mask. The parameters of helical symmetry (number of subunits per turn and pitch) must be determined by indexing the computed diffraction patterns. If necessary, simple spline-fitting procedures may be employed to 'straighten' images of curved particles (Egelman, 1986), and the image data may be reinterpolated (Owen *et al.*, 1996) to provide more precise sampling of the layer-line data in the computed transform. Once a preliminary 3D structure is available, a much more sophisticated refinement of all the helical parameters can be used to unbend the helices onto a predetermined average helix so that the contributions of all parts of the image are correctly treated (Beroukhim & Unwin, 1997). The layer-line data are extracted from each particle transform and two phase-origin corrections are made: one to shift the phase origin to the helix axis (at the centre of the particle image) and the other to correct for effects caused by having the helix axis tilted out of the plane normal to the electron beam in the electron microscope. The layer-line data are separated out into near- and far-side data, corresponding to contributions from the near and far sides of each particle imaged. The relative rotations and translations needed to align the different transforms are determined so the data may be merged and a 3D reconstruction computed by Fourier–Bessel inversion procedures (DeRosier & Moore, 1970). Determination of the absolute hand requires comparison of a pair of images recorded with a small tilt of the specimen between the views (Finch, 1972). An iterative, real-space helical reconstruction method that uses single-particle processing procedures and offers an alternative to the Fourier–Bessel strategy has recently been developed and provides clear advantages for studying structures with imperfect helical symmetry (Egelman 2000, 2007*a*,*b*). Back-projection approaches offer a robust way of dealing with irregular helices or those with discontinuities or seams (Sosa & Milligan, 1996; Sosa *et al.*, 1997).

19.6.5.3. Icosahedral particles

The typical strategy for processing and 3D reconstruction of icosahedral particles consists of the following steps. First, a series of micrographs of a monodisperse distribution of particles, normally suspended over holes in a perforated carbon support film, is recorded. After digitization of the micrographs, individual particle images are boxed and floated with a circular mask. The astigmatism and defocus of each micrograph is measured from the sum of intensities of the Fourier transforms of all particle images (Zhou *et al.*, 1996; Mallick *et al.*, 2005), or by a more automatic procedure applied to the whole micrograph (Mindell & Grigorieff, 2003). Auto-correlation techniques are then used to estimate the particle phase origins, which coincide with the centre of each particle where all rotational symmetry axes intersect (Olson & Baker, 1989). The view orientation of each particle, defined by three Eulerian angles, was originally determined by means of common and cross-common lines techniques (Crowther *et al.*, 1970; Crowther, 1971; Fuller *et al.*, 1996; Baker *et al.*, 1999; Thuman-Commike & Chiu, 2000), but is now more commonly determined with the aid of model-based, template-matching procedures (*e.g.* Baker & Cheng, 1996; Castón *et al.*, 1999; Grigorieff, 2007; Yan, Dryden *et al.*, 2007). Once a set of self-consistent particle images is available, an initial low-resolution 3D reconstruction is computed by merging these data with Fourier–Bessel (Crowther, 1971) or Fourier–Cartesian (*e.g.* Ji *et al.*, 2006) methods. This reconstruction then serves as a reference for refining the orientation, origin and CTF parameters of each of the included particle images, for rejecting 'bad' images, and for increasing the size of the data set by including new particle images from additional micrographs taken at different defocus levels. A new reconstruction, computed from the latest set of images, serves as a new reference and the above refinement procedure is repeated until no further improvements as measured by the reliability criteria mentioned above are made. Determination of the absolute hand of the structure requires the recording and processing of a pair of images taken with a known, small relative tilt of the specimen between the two views (Belnap *et al.*, 1997; Rosenthal & Henderson, 2003). In the past decade, 3D cryoTEM analysis of icosahedral viruses at sub-nanometre resolution has fully matured and near-atomic level (<4 Å) maps (*e.g.* Yu, Jin & Zhou, 2008; Zhang *et al.*, 2008; Zhou, 2008; Chen *et al.*, 2009) will certainly become more commonplace.

19.6.5.4. Electron cryo-tomography

This section is probably more appropriate to a cell-biology textbook than to *International Tables for Crystallography*, but we include it because of its growing importance and potential in the field of structural biology. Good reviews are to be found in Frank (2006*a*) and in three special issues of *Journal of Structural Biology* already mentioned in Table 19.6.5.1. Briefly, a tilt series of micrographs of the specimen is recorded, typically through an angular range of ±60° or ±70°, and this is used, by *R*-weighted back projection, to produce a 3D map of the specimen. This can be further processed, segmented, coloured, rendered and interpreted (*e.g.* Medalia *et al.*, 2002; Nicastro *et al.*, 2005).

Electron cryo-tomography is typically used in two different ways. First, it is used to describe the structure of a unique, non-repeating biological sample such as a cell or organelle, possibly to observe how the structure can change or to explore the diversity of structures that occur. Second, it is used to produce a 3D map (tomogram) of a structure that includes many copies of identical assemblies, such as the trimeric glycoprotein surface spikes on HIV (*e.g.* Liu, Bartesaghi *et al.*, 2008). Individual 3D volumes are then selected from a number of tomograms to give several hundred or thousand sub-tomogram volumes, each of which contains a single copy of the object of interest viewed in an arbitrary direction. By averaging appropriately aligned 3D volumes, which represent a variety of orientations of presumed, identical structures, it is then possible to carry out the same type of averaging as described for all the other specimen types. Although the resolutions attained in the raw tomograms at present (~2009) range at best between 4 and 5 nm, and signal-to-noise considerations (Rosenthal & Henderson, 2003) suggest that the resolution of raw electron cryo-tomograms can never reach better than 1.5–2.0 nm, the procedure of sub-tomogram averaging of identical structures or substructures can, in principle, improve the resolution greatly. This second application of electron cryo-tomography thus fits perfectly into the context of *International Tables*. Examples of this application include the works by Fernandez *et al.* (2006), Zanetti *et al.* (2006), Liu, Bartesaghi *et al.* (2008), Zhu *et al.* (2008) and Zanetti *et al.* (2009). In the area of cellular tomography, the use of high-pressure freezing and cryo-sectioning followed by electron cryo-tomography is most promising (Zuber *et al.*, 2005, 2008; Salje *et al.*, 2009).

19.6.6. Visualization, modelling and interpretation of results

The explosive growth in the number of structures of macromolecules and complexes that are now being determined at sub-nanometre resolutions has spawned the development of numerous tools that enable investigators to visualize, model and interpret their results. Generally, after assessing a global view of the gross morphology of a molecule, one quickly zooms in to explore finer and finer details. A major challenge, especially with density maps of increasing size (*e.g.* >512 pixels), is to perform these operations in real time. Several computer-graphics applications have emerged that satisfy a variety of requirements for visualizing cryoTEM maps. Examples of specific programs include *Chimera* (Pettersen *et al.*, 2004; Goddard *et al.*, 2005; Goddard & Ferrin, 2007; Goddard *et al.*, 2007), *colorRNA* (LeBarron *et al.*, 2007), *MODELLER* (Eswar *et al.*, 2007), *Python Molecular Viewer* (*PMV*) (Sanner, 1999; Gillet *et al.*, 2005), *Vision* (Sanner, 2005); *VMD* (Hsin *et al.*, 2008) and *VolRover* (Bajaj *et al.*, 2005). Many of these programs as well as most of the more common, multipurpose reconstruction programs provide tools for generating animations that can be used to help simulate data and that are particularly useful in communicating results to scientific as well as lay audiences (McGill, 2008). Additional useful tools allow one to produce space-filling, cartoon-like renderings of molecules that reduce unnecessary detail and hence are more easily understood (Goodsell, 2005).

Visualization tools merely provide an entryway to more careful scrutiny and interpretation of structure. When viewed in the context of existing biochemical and molecular studies as well as complementary X-ray crystallographic and other biophysical measurements, structural results provide a basis for understanding how molecules function. Even in the absence of complementary, high-resolution structural data, since 3D cryoTEM maps often reach sub-nanometre resolutions, it is usually possible to recognize characteristic, secondary structural elements like α-helices and large β-sheets in proteins. Several programs help identify such elements (Jiang, Baker *et al.*, 2001; Kong & Ma, 2003; Kong *et al.*, 2004; Baker *et al.*, 2007), and this then facilitates the process of defining and segmenting molecular envelopes (*e.g.* Volkmann, 2002; Baker, Yu *et al.*, 2006) and elucidating protein folds (Zhou *et al.*, 2001; Chiu *et al.*, 2002; Kovacs *et al.*, 2007; Lindert, Staritzbichler *et al.*, 2009). When

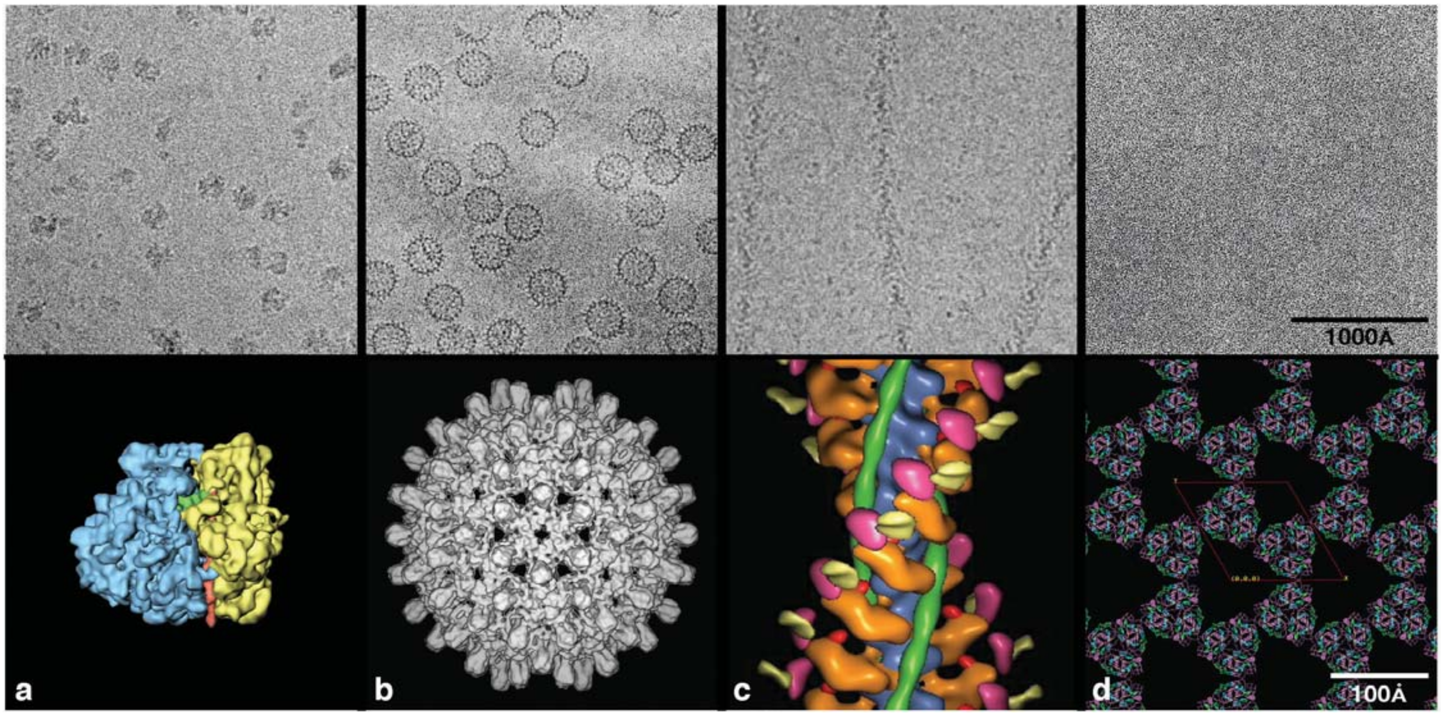

Figure 19.6.7.1
Examples of macromolecules studied by cryoTEM and 3D image reconstruction and the resulting 3D structures (bottom row) after cryoTEM analysis. All micrographs (top row) are displayed at ~170 000× magnification and all models at ~1 200 000× magnification. (*a*) A single particle without symmetry. The micrograph shows 70S *E. coli* ribosomes complexed with mRNA and fMet-tRNA. The surface-shaded density map, made by averaging 73 000 ribosome images from 287 micrographs, has a resolution of 11.5 Å. The 50S and 30S subunits and the tRNA are coloured blue, yellow and green, respectively. The identity of many of the protein and RNA components is known and some RNA double helices are clearly recognizable by their major and minor grooves (*e.g.* helix 44 is shown in red). Courtesy of J. Frank, using data from Gabashvili *et al.* (2000). (*b*) A single particle with symmetry. The micrograph shows hepatitis B virus cores. The 3D reconstruction, at a resolution of 7.4 Å, was computed from 6384 particle images taken from 34 micrographs. From Böttcher *et al.* (1997). (*c*) A helical filament. The micrograph shows actin filaments decorated with myosin S1 heads containing the essential light chain. The 3D reconstruction, at a resolution of 30–35 Å, is a composite in which the differently coloured parts are derived from a series of difference maps that were superimposed on F-actin. The components include: F-actin (blue), myosin heavy-chain motor domain (orange), essential light chain (purple), regulatory light chain (yellow), tropomyosin (green) and myosin motor domain N-terminal beta-barrel (magenta). Courtesy of A. Lin, M. Whittaker & R. Milligan (Scripps Research Institute, La Jolla). (*d*) A 2D crystal: light-harvesting complex LHCII at 3.4 Å resolution. The model shows the protein backbone and the arrangement of chromophores in a number of trimeric subunits in the crystal lattice. In this example, image contrast is too low to see any hint of the structure without image processing (see also Fig. 19.6.4.2). Courtesy of W. Kühlbrandt (Max-Planck-Institute for Biophysics, Frankfurt).

complementary data from X-ray crystallography are available for individual components of a macromolecule, or perhaps even the entire complex, so-called pseudo-atomic models can be produced that closely match the cryoTEM map and lead to more accurate and reliable data interpretation.

Pseudo-atomic models were originally constructed by docking X-ray-derived models manually into cryoTEM density maps (Wang *et al.*, 1992; Rayment *et al.*, 1993; Stewart *et al.*, 1993). However, qualitative procedures like these quickly spurred the development of rigorous, quantitative tools for fitting models into 3D maps as rigid bodies (Volkmann & Hanein, 1999; Wriggers *et al.*, 1999; Roseman, 2000; Rossmann *et al.*, 2001; Wriggers & Chacon, 2001; Chacón & Wriggers, 2002; Navaza *et al.*, 2002; Birmanns & Wriggers, 2003) and several of these methods have been the subject of review articles (Volkmann & Hanein, 2003; Fabiola & Chapman, 2005). The limitations inherent in assuming that vitrified molecules retain the same conformation found in crystals spawned the evolution of numerous flexible fitting and refinement methods (*e.g.* Wriggers & Birmanns, 2001; Gao & Frank, 2005; Velazquez-Muriel *et al.*, 2006; Tan *et al.*, 2008; Dimaio *et al.*, 2009). Many of the flexible fitting methods are based on normal-mode analysis (Tama *et al.*, 2003, 2004*a*,*b*; Bahar & Rader, 2005; Suhre *et al.*, 2006; Gorba *et al.*, 2008) and on molecular and damped dynamics (Kovacs *et al.*, 2008; Orzechowski & Tama, 2008; Trabuco *et al.*, 2008, 2009). When no X-ray structure is available to guide pseudo-atomic modelling of the cryoTEM map, it is still feasible to apply hybrid approaches (*e.g.* iterative structure-based sequence alignment, fitting and refinement) and construct a series of homology models (Topf *et al.*, 2005; Baker, Jiang *et al.*, 2006; Topf *et al.*, 2006; Lindert, Stewart & Meiler, 2009) that can be assessed to help identify reliable candidates (Shacham *et al.*, 2007; Velazquez-Muriel & Carazo, 2007).

19.6.7. Trends

The new generation of intermediate-voltage (~300 kV) FEG microscopes with stable cold stages is now making it much easier to obtain higher-resolution images that, by use of larger defocus values, have good image contrast at both very low and very high resolution. The greater contrast at low resolution greatly facilitates particle-alignment procedures, and the increased contrast resulting from the high-coherence illumination helps to increase the signal-to-noise ratio for the structure at high resolution. Cold stages are constantly being improved, with several liquid-helium stages developed in the 1990s (Fujiyoshi *et al.*, 1991; Zemlin *et al.*, 1996). Two such stages are commercially available from JEOL and FEI.

Finally, some likely trends in the next few years include the following.

(1) Increased automation including:
  (*a*) specimen loading (Lefman *et al.*, 2007);
  (*b*) the recording of micrographs (Potter *et al.*, 1999; Zhang *et al.*, 2003; Lei & Frank, 2005; Suloway *et al.*, 2005; Zheng *et al.*, 2006; Nickell *et al.*, 2007; Yoshioka *et al.*, 2007; Shi *et al.*, 2008; Suloway *et al.*, 2009; Zhang *et al.*, 2009);
  (*c*) particle picking (Short, 2004; Zhu *et al.*, 2004; Chen & Grigorieff, 2007; Plaisier *et al.*, 2007; Woolford *et al.*, 2007; Sorzano *et al.*, 2009; Voss *et al.*, 2009), CTF estimation (*e.g.* Huang *et al.*, 2003; Fernando & Fuller, 2007; Jonic *et al.*, 2007; Sorzano *et al.*, 2007);
  (*d*) 3D reconstructions (*e.g.* Jiang, Li *et al.*, 2001; Mouche *et al.*, 2003; Stagg *et al.*, 2006; Yan, Sinkovits & Baker, 2007; Lander *et al.*, 2009); and
  (*e*) high-performance computing (*e.g.* Bilbao-Castro *et al.*, 2006; Castano-Diez *et al.*, 2007; Yang *et al.*, 2007; Castano-Diez *et al.*, 2008; Fernandez, 2008; Bilbao-Castro *et al.*, 2009).

(2) Introduction of better electronic cameras including:
  (*a*) lens-coupled CCDs (*e.g.* Maki-Yonekura & Yonekura, 2008);
  (*b*) complementary metal-oxide semiconductor (CMOS) sensors, which detect electrons directly. These are based on a technology used in many digital cameras and are displacing CCD technology for larger area detectors (Faruqi *et al.*, 2005; Milazzo *et al.*, 2005; Turchetta *et al.*, 2006; Xuong *et al.*, 2007; Jin *et al.*, 2008);
  (*c*) back-thinned CMOS sensors (McMullan, Faruqi *et al.*, 2009); and
  (*d*) silicon pixel detectors (*e.g.* Faruqi *et al.*, 2003; McMullan *et al.*, 2007).

(3) Increased use of dose-fractionated, tomographic tilt series to extend EM studies to the domain of larger supramolecular and cellular structures (*e.g.* McEwen *et al.*, 1995; Medalia *et al.*, 2002; Lucic *et al.*, 2005; Nicastro *et al.*, 2005, 2006; Jensen & Briegel, 2007; Zheng *et al.*, 2007; Salje *et al.*, 2009).

(4) Evaluation of C_c correctors for cryo-tomography of thicker specimens (Kabius *et al.*, 2009).

(5) The development and use of phase plates (*e.g.* Danev & Nagayama, 2001; Majorovits *et al.*, 2007; Danev & Nagayama, 2008; Nagayama & Danev, 2008; Danev *et al.*, 2009).

We are greatly indebted to all our colleagues in San Diego and Cambridge for their insightful comments and suggestions, to B. Böttcher, R. Crowther, J. Frank, W. Kühlbrandt and R. Milligan for supplying images used in Fig. 19.6.7.1, which gives some examples of the best work done recently, and to N. Olson for identifying numerous recent citations. TSB was supported in part by grant R37 GM-033050 from the National Institutes of Health.

Chapter 19.7. Nuclear magnetic resonance (NMR) spectroscopy

K. Wüthrich

19.7.1. Complementary roles of NMR in solution and X-ray crystallography in structural biology

X-ray diffraction in crystals and NMR in solution can both be used to determine the complete three-dimensional structure of biological macromolecules, and to date a significant number of globular protein structures have been independently determined in crystals and in solution (Billeter, 1992). Particularly detailed comparisons of the two states have been made for the α-amylase inhibitor Tendamistat, which also included solving the crystal structure by molecular replacement with the NMR structure (Braun *et al.*, 1989). The dominant impression is one of near-identity of the molecular architecture in solution and in single crystals, which holds for the polypeptide backbone as well as the core side chains.

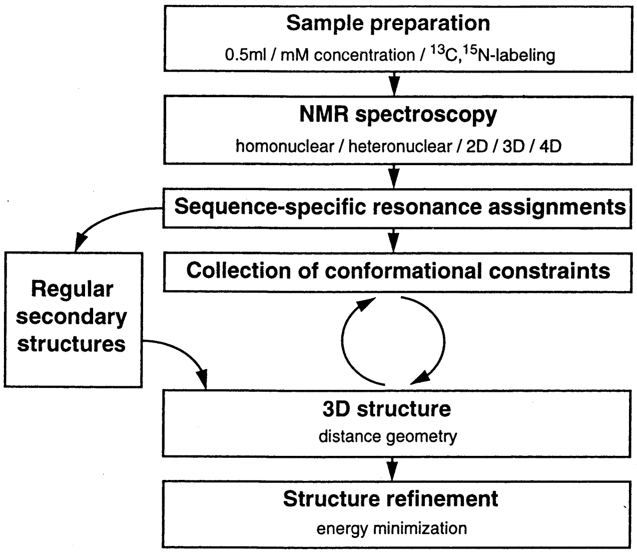
Although the presently available results show that there is usually close coincidence between both the global molecular architecture and the detailed arrangement of the molecular core in corresponding X-ray and NMR structures of globular proteins, there is also extensive complementarity in the information that is accessible with the two methods: X-ray diffraction can provide the desired information for big molecules and multimolecular assemblies, whereas NMR structure determination is limited to smaller systems [recently introduced new experiments enable solution NMR measurements for molecular weights of 100 000 and beyond (Pervushin *et al.*, 1997; Riek *et al.*, 1999)]. NMR measurements in turn provide quantitative information on both very rapid motions on the subnanosecond timescale (Otting *et al.*, 1991; Peng & Wagner, 1992) and slower dynamic processes (Wüthrich, 1986) which are not manifested in the X-ray data. Examples of low-frequency intramolecular mobility are the ring flips of phenylalanine and tyrosine (Wüthrich & Wagner, 1975), exchange of interior hydration water molecules with the bulk solvent (Otting *et al.*, 1991), and interconversion of disulfide bonds between the *R* and *S* chiral forms (Otting *et al.*, 1993). NMR studies of amide proton exchange and *cis–trans* isomerization of *Xxx*—Pro peptide bonds (Wüthrich, 1976, 1986) afford additional insight into conformational equilibria in the protein core. Finally, in all instances where a biological macromolecule cannot be crystallized, NMR is currently the only method capable of providing a three-dimensional structure.

Overall, X-ray crystal structures and NMR solution structures provide qualitatively different information on the molecular surface. In the crystals, a sizeable proportion of surface amino-acid side chains are subject to similar packing constraints in protein–protein interfaces as the interior side chains in the protein core, and therefore they are rather precisely defined by the X-ray diffraction data. In NMR solution structures determined according to a standard protocol (Wüthrich, 1995), the surface is usually largely disordered. Surface disorder in NMR structures may in part arise from scarcity of nuclear Overhauser effect (NOE) distance constraints and packing constraints near the protein surface, but, in turn, scarcity of NOE constraints is often a direct consequence of dynamic disorder. Additional NMR experiments that are not part of a standard structure determination protocol can provide information needed for more detailed characterization of the molecular surface, but care must be exercised in the data analysis because of the presence of a multitude of equilibria between two or multiple transient local conformational states, of which the relative populations are usually not independently known.

19.7.2. A standard protocol for NMR structure determination of proteins and nucleic acids

An NMR structure determination involves sample preparation, NMR measurements, assignment of the NMR lines to individual atoms in the polymer chain, collection of conformational constraints, and structure calculation and refinement, where in present practice the sequence of steps usually corresponds to the flow diagram of Fig. 19.7.2.1. As is also indicated in Fig. 19.7.2.1, it is a special feature of protein structure determination by NMR that the secondary polypeptide structure, including the connections between individual segments of regular secondary structure, may be known early on from the data used for obtaining the resonance assignments, *i.e.* before the structure calculation is even started.

For the sample preparation, homogeneous macromolecular material is dissolved at about 1 m*M* concentration in 0.5 ml of water. The ionic strength, pH and temperature, and possibly the concentration of additives, may then be adjusted, for example, to ensure near-physiological conditions, or denaturing conditions *etc*. The NMR study will often include the preparation of compounds enriched with ^{15}N and/or ^{13}C, and possibly with ^{2}H (Kay & Gardner, 1997). Uniformly isotope-labelled recombinant proteins are routinely obtained by expression in *Escherichia coli* bacteria grown on minimal media. For RNA and DNA, isotope-labelling techniques are more involved, but labelled nucleic acids will also be commonly available in the future. Being able to work



Sample preparation
0.5ml / mM concentration / ^{13}C,^{15}N-labeling
NMR spectroscopy
homonuclear / heteronuclear / 2D / 3D / 4D
Sequence-specific resonance assignments
Regular secondary structures
Collection of conformational constraints
3D structure
distance geometry
Structure refinement
energy minimization

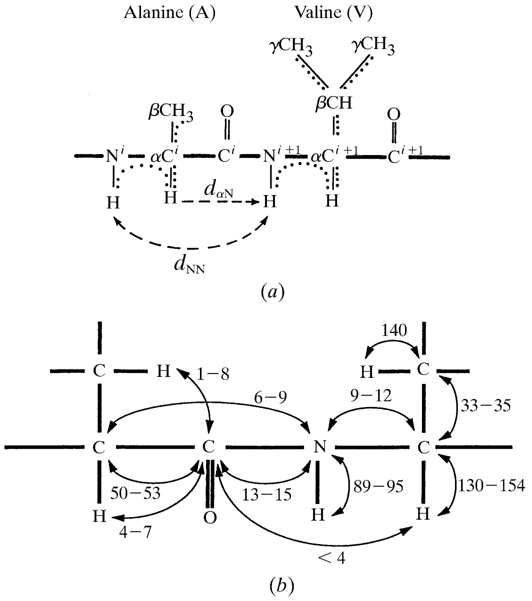

Figure 19.7.2.2

(*a*) Sequential resonance assignment based on sequential ^{1}H–^{1}H NOEs. In the dipeptide segment -Ala-Val- the dotted lines indicate ^{1}H–^{1}H relations which can be established by scalar through-bond spin–spin couplings. The broken arrows connect pairs of protons in sequentially neighbouring residues, *i* and $i + 1$, which are related by ^{1}H–^{1}H NOEs that manifest short sequential distances $d_{\alpha N}$ (between αCH and the amide proton of the following residue) and d_{NN} (between the amide protons of neighbouring residues). (*b*) Segment of a polypeptide chain with indication of the scalar spin–spin couplings that provide the basis for obtaining sequential assignments by triple-resonance experiments with uniformly ^{13}C/^{15}N labelled proteins.

with solutions is generally considered to be a great asset of the NMR method, but there are also potential inherent difficulties. For example, in the course of an investigation it may be nontrivial to achieve identical solution conditions in different NMR samples of the same compound, the absence of which typically results in small chemical-shift differences that slow down the combined analysis of different NMR spectra.

The demands on NMR experiments for macromolecular structure determination are currently met by multidimensional NMR at high polarizing magnetic fields (Wüthrich, 1986; Ernst *et al.*, 1987; Cavanagh *et al.*, 1996). With increasing molecular size and concomitant increase of the number of NMR peaks, it becomes more and more difficult to resolve and assign the individual resonances. In heteronuclear three- or four-dimensional (3D or 4D) spectra recorded with compounds that are uniformly labelled with ^{15}N and/or ^{13}C, the peaks are spread out in a third and possibly fourth dimension along the ^{15}N and ^{13}C chemical-shift axes (for a review, see Bax & Grzesiek, 1993). Additional labelling with ^{2}H results in slower spin-relaxation rates and hence improved sensitivity and spectral resolution. Although this approach provides ^{13}C and ^{15}N NMR information, which may be used to support the structure determination (*e.g.* Wishart *et al.*, 1991) and to provide supplementary information on dynamic features of the molecule studied, the key purpose of heteronuclear NMR experiments is to enhance the spectral resolution for studies of protons and thus to obtain the maximum possible number of ^{1}H NMR-based conformational constraints.

Resonance assignments in biopolymers are obtained using the sequential assignment strategy (Dubs *et al.*, 1979; Billeter *et al.*, 1982; Wagner & Wüthrich, 1982). Unique segments of two or several sequentially adjoining amino-acid residues are identified by NMR experiments and then attributed to discrete positions in the polypeptide chain by comparison with the chemically determined amino-acid sequence. The desired relations between protons in sequentially neighbouring amino-acid residues *i* and $i + 1$ can be established by nuclear Overhauser effects (NOEs), manifesting a close approach between αCH_i and NH_{i+1} ($d_{\alpha N}$), NH_i and NH_{i+1} (d_{NN}) (Fig. 19.7.2.2*a*), and possibly βCH_i and NH_{i+1} ($d_{\beta N}$) (Wüthrich, 1986). For *Xxx*—Pro dipeptide segments, corresponding connectivities are observed with δCH_2 of Pro in the place of the amide proton. For small proteins with up to about 100 amino-acid residues, NOE-based sequential assignments can rely entirely on homonuclear ^{1}H NMR experiments, and for somewhat bigger proteins they can be established based on the improved resolution of 3D NMR experiments with ^{15}N-labelled proteins. No prior knowledge of the polypeptide conformation is needed, since at least one of the two distances $d_{\alpha N}$ or d_{NN} (Fig. 19.7.2.2*a*) is always sufficiently short to be observed by NOEs (Billeter *et al.*, 1982). A further attractive feature of this approach is that the identification of the sequential NOEs forms an integral part of the data collection for the protein structure determination (see below). Sequential assignments can alternatively be obtained entirely *via* heteronuclear scalar couplings, using recombinant isotope-labelled proteins (Fig. 19.7.2.2*b*). Using 3D and 4D heteronuclear triple-resonance experiments, the resonance lines of sufficiently large mutually overlapping fragments of the polypeptide chain are grouped together to enable sequence-specific resonance assignments (for a review, see Bax & Grzesiek, 1993). With the implementation of transverse relaxation-optimized spectroscopy (TROSY) elements (Pervushin *et al.*, 1997) into triple-resonance experiments (Salzmann *et al.*, 1998), backbone resonance assignments *via* the spin–spin couplings of Fig. 19.7.2.2(*b*) can be performed with molecular weights of 100 000 and beyond. For nucleic acids, assignment procedures were largely patterned after those used for proteins and have been used successfully for fragments with 40 nucleotides and beyond.

NOE upper-distance constraints contain the crucial information needed for macromolecular structure determination (Wüthrich, 1986, 1989). To obtain a high-quality structure, the maximum possible number of NOE conformational constraints must be collected as input for the structure calculation. This is accomplished by using the chemical-shift lists obtained as a result of the sequence-specific resonance assignments to attribute the cross peaks in 2D [^{1}H, ^{1}H]-NOESY spectra, or 3D and 4D heteronuclear-resolved [^{1}H, ^{1}H]-NOESY spectra, to distinct pairs of hydrogen atoms. As indicated in Fig. 19.7.2.1, this data collection is achieved in several cycles, where ambiguities in the NOESY cross-peak assignments can usually be resolved by reference to preliminary structures calculated from incomplete input data sets (Güntert *et al.*, 1993). In present practice, each individual NOE constraint has the format of an allowed distance range, which circumvents intrinsic difficulties that might arise from attempts at quantitative distance measurements, and which is also adjusted to account for possible effects from internal mobility. The lower limit is usually taken to correspond to the sum of two hydrogen atomic radii, *i.e.* 2.0 Å, and the NOE intensities are translated into corresponding upper bounds, typically in steps of 2.5, 3.0 and 4.0 Å. Supplementary conformational constraints, for example, from spin–spin coupling constants (Wüthrich, 1986), residual dipole–dipole couplings (Tjandra & Bax, 1997), pseudocontact shifts and relaxation effects near paramagnetic centres (Banci *et al.*, 1998) *etc.*, are represented in the input by similar allowed ranges, which account for the internal mobility of the 3D structures and the limited accuracy of the individual measurements. Initially, NMR structures were calculated using distance-geometry techniques, and subsequently the principles of distance geometry have been introduced into molecular-dynamics programs in Cartesian coordinates (Brünger *et al.*, 1986) or in torsion-angle space (Güntert *et al.*, 1997). Model calculations performed in conjunction with the initial protein structure determinations had shown that NMR structure calculation depends critically on the density of NOE distance constraints, while it is remarkably robust with regard to low precision of the individual distance constraints (Havel & Wüthrich, 1985). For the common presentation of an NMR structure, one considers the result of a single structure calculation as representing one molecular geometry that is compatible with the NMR data. To investigate further whether or not this solution is unique, the calculation is repeated with different boundary conditions, where for each calculation, convergence is judged by the residual constraint violations. All satisfactory solutions, by this criterion, are included in a group of conformers that is used to represent the NMR structure (Fig. 19.7.2.3). The precision of the structure determination is reflected by the dispersion among this group of conformers. In proteins, larger variations are typically observed near the chain ends, in exposed loops and for surface amino-acid side chains, which contrasts with the well defined core. For nucleic acids, the 'global folds', for example, formation of duplexes, triplexes, quadruplexes, or loops, can be well defined by NMR, but because of the short range of the NOE distance measurements, certain 'long-range' features, for example, bending of DNA duplexes, may be more difficult to characterize.

19.7.3. Combined use of single-crystal X-ray diffraction and solution NMR for structure determination

The chemical shifts in proteins or nucleic acids cannot be calculated with sufficiently high precision from the X-ray crystal structures to predict the NMR spectra reliably. This limits the extent to which improved efficiency of an NMR structure determination may be derived from knowledge of the corresponding crystal structure. Nonetheless, for resonance assignments with sequential NOEs, information on the type of connectivity to look for in specified polypeptide segments may be derived. The X-ray structure may also tentatively be used as a starting reference to resolve ambiguities in the assignment of NOE distance constraints (Güntert *et al.*, 1993), which may help to reduce the number of cycles needed to collect the input data for a high-quality structure determination (Fig. 19.7.2.1).

An attractive possibility for combined use of X-ray and NMR data has in the past arisen in situations where both a low-resolution crystallographic electron-density map and a secondary-structure determination by NMR are available. As mentioned before, NMR secondary-structure determination in proteins usually derives directly from the backbone resonance assignments (Wishart *et al.*, 1991; Wüthrich *et al.*, 1984) and does not depend on the availability of a complete three-dimensional structure. Since the covalent connections between regular secondary-structure elements can often also be unambiguously determined, this NMR information may be helpful in tracing the electron-density map for the determination of the corresponding X-ray crystal structure (Kallen *et al.*, 1991). Furthermore, since identical global architectures are usually found for corresponding crystal and solution structures of globular proteins, NMR structures have been used to solve the corresponding crystal structure by molecular replacement (*e.g.* Braun *et al.*, 1989). Considering the ease with which high-quality X-ray data are obtained nowadays once suitable crystals are available, it remains to be seen whether this kind of combined use of data obtained with the two methods will also play a role in the future.

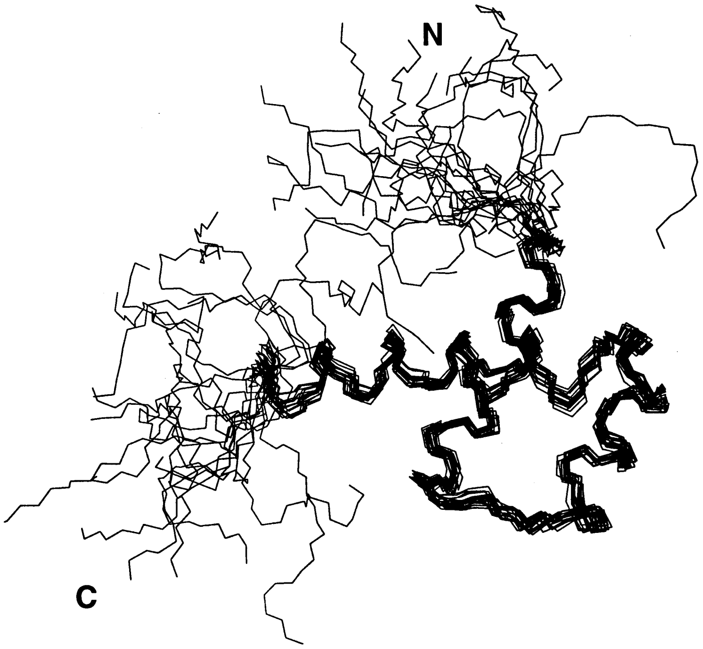

Figure 19.7.2.3
Polypeptide backbone of 19 energy-refined conformers selected to represent the NMR solution structure of the *Antennapedia* homeodomain. From residues 7 to 59, the structure is well defined by the NMR data. The chain-terminal segments 0–6 and 60–67 are disordered, and additional NMR studies showed that these terminal segments behave like 'flexible tails'. [Drawing prepared with the atomic coordinates from Qian *et al.* (1989).]

19.7.4. NMR studies of solvation in solution

In NMR structures, the location of hydration water molecules is determined by the observation of NOEs between water protons and hydrogen atoms of the polypeptide chain. In contrast to the observation of hydration water in X-ray crystal structures, this information is not routinely collected within the scope of a standard protocol for NMR structure determination (Fig. 19.7.2.1), but requires additional experiments (Otting *et al.*, 1991). Because the NOE decreases with the sixth power of the ^{1}H–^{1}H distance, only water molecules in a first hydration layer are typically observed. The NOE intensity is further related to a correlation function describing the stochastic modulation of the dipole–dipole coupling between the interacting protons, which may be governed either by the Brownian rotational tumbling of the hydrated protein molecule or by interruption of the dipolar interaction through translational diffusion of the interacting spins, whichever is faster (Otting *et al.*, 1991). Interior hydration waters are typically observed in identical locations in corresponding crystal and solution structures, but NMR provides additional information on molecular mobility. Completely buried hydration water molecules have thus been found to exchange with the bulk solvent at rates corresponding to millisecond residence times in the protein hydration sites, and measurements with nuclear magnetic relaxation dispersion also revealed exchange rates on the microsecond to nanosecond timescale (Denisov *et al.*, 1996). For surface hydration water, the lifetimes in the hydration sites are typically even shorter, and NMR measures the average duration of these 'visits' (Otting *et al.*, 1991;

in an alternative analysis of the NMR data, surface hydration has been characterized by reduced diffusion rates of the water, without specifying individual hydration sites; Brüschweiler & Wright, 1994). Diffraction experiments, on the other hand, probe the total fraction of time that a water molecule spends in a particular hydration site, but they are insensitive to the residence time at that site on any particular visit. Furthermore, while hydration water molecules in protein crystals are observed in discrete surface sites that are not blocked by direct protein–protein contacts, the entire surface of a protein in aqueous solution is covered with water molecules. Overall, the NMR view of hydration in solution, which has also been rationalized with long-time molecular-dynamics simulations (*e.g.* Billeter *et al.*, 1996; Brunne *et al.*, 1993), is largely complementary to crystallographic data on hydration.

19.7.5. NMR studies of rate processes and conformational equilibria in three-dimensional macromolecular structures

Similar to the aforementioned hydration studies, information on intramolecular rate processes in macromolecular structures cannot usually be obtained from the standard protocol for NMR structure determination (Fig. 19.7.2.1), but results from additional experiments. The complementarity of such NMR information to crystallographic data is well illustrated by the 'ring flips' of phenylalanine and tyrosine (Wüthrich, 1986). The observation of these ring-flipping motions in the basic pancreatic trypsin inhibitor (BPTI) (Wüthrich & Wagner, 1975) was a genuine surprise for the following reasons. In the refined X-ray crystal structure of BPTI, the aromatic rings of phenylalanine and tyrosine are among the side chains with the smallest temperature factors. For each ring, the relative values of the *B* factors increase toward the periphery, so that the largest positional uncertainty is indicated for carbon atom 4 on the symmetry axis through the $C^{\beta}-C^{1}$ bond, rather than for the carbon atoms 2, 3, 5 and 6 (Fig. 19.7.5.1), which undergo extensive movements during the ring flips. Theoretical studies then showed that the crystallographic *B* factors sample multiple rotation states about the $C^{\alpha}-C^{\beta}$ bond, whereas the ring flips about the $C^{\beta}-C^{1}$ bond seen by NMR are very rapid 180° rotations connecting two indistinguishable equilibrium orientations of the ring. The *B* factors do not manifest these rotational motions because the populations of all non-equilibrium rotational states about the $C^{\beta}-C^{1}$ bond are vanishingly small. The ring-flip phenomenon is now a well established feature of globular proteins, manifesting ubiquitous low-frequency internal motions with activation energies of 60–100 kJ mol^{-1}, amplitudes of $\gtrsim 1.0$ Å and activation volumes of about 50 Å^3 (Wagner, 1980), and involving concerted displacement of numerous groups of atoms (Fig. 19.7.5.1).

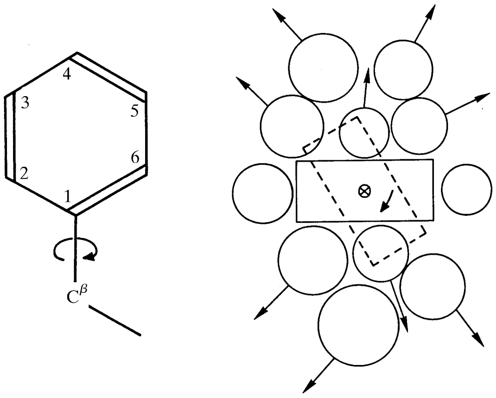

Figure 19.7.5.1
180° ring flips of tyrosine and phenylalanine about the $C^{\beta}-C^{1}$ bond. On the left, the atom numbering is given and the χ^2 rotation axis is identified with an arrow. The drawing on the right presents a view along the $C^{\beta}-C^{1}$ bond of a flipping ring in the interior of a protein, where the broken lines indicate a transient orientation of the ring plane during the flip. The circles represent atom groups near the ring, and arrows indicate movements of atom groups during the ring flip (Wüthrich, 1986).

Chapter 19.8. Use of *SPIDER* and *SPIRE* in image reconstruction

A. Leith, W. Baxter and J. Frank

19.8.1. Introduction

SPIDER (System for Processing Image Data in Electron microscopy and Related fields) was one of the earliest image-processing packages for single-particle reconstruction and electron tomography. It was first released in 1978, and has been continually improved and updated since then (Frank *et al.*, 1981, 1996; Baxter *et al.*, 2007; Shaikh *et al.*, 2008; Yang *et al.*, 2007). It is currently available as free open-source code under Gnu Public License (GPL).

In its most common usage, *SPIDER* allows a researcher to create a three-dimensional (3D) reconstruction of a macromolecule from a collection of transmission electron micrographs, interpreted as projections showing the molecule in different orientations. Using cryo-electron microscopy these methods, pioneered by Joachim Frank at the Wadsworth Center in Albany (see Frank, 2006), have recently allowed researchers to determine the 3D structures of several macromolecular complexes at near-atomic resolution (~3.8–4.5 Å; Zhou, 2008). These methods provide a way of studying the structure of such complexes in a more natural environment than is possible using X-ray crystallography and of studying conformational changes of molecular machines as they perform their work (Saibil, 2000).

One way in which *SPIDER* differs from most other software for single-particle reconstruction [*Imagic* (van Heel *et al.*, 1996; Chapter 19.9), *Frealign* (Grigorieff, 2007), *EMAN2* (Tang *et al.*, 2007; Chapter 19.10), *SPARX* (Hohn *et al.*, 2007) and *Xmipp* (Sorzano *et al.*, 2004)] is that it provides alternative methods for many procedures and thus can serve as a developmental platform for testing different approaches to single-particle reconstruction. For instance, alternative alignment operations and statistical analysis operations can be combined inside scripts to investigate different approaches to overcoming molecular heterogeneity.

The prime reasons for the continued success of *SPIDER* are its validated reputation for providing the highest-resolution reconstructions, its ease of installation and its comprehensive documentation, which is constantly being updated (Shaik *et al.*, 2008). *SPIDER*'s procedure language makes it easy to use for controlling the flow of a complex train of operations and addressing problems related to heterogeneity of particles. With the Quick Start Guide and tutorials as an introduction, a new user can quickly acquire competence in the procedure language with only a few hours' introduction.

The *SPIDER* system consists of six major components:

(i) *SPIDER*: the Fortran program with a command interpreter recognizing *SPIDER* commands and procedure calls.

(ii) *SPIDER* procedures: text files containing *SPIDER* commands, parameters, and script-specific operations for conditional execution and looping (see Section 19.8.3).

(iii) *Web*: a graphical user interface (GUI) for use in Linux and OS X (Frank *et al.*, 1996). *Web* is available in two different versions, the original X-Window version written in C and a newer Java version.

(iv) *SPIDER* reconstruction engine (*SPIRE*), which represents a metastructure that enables procedure files, file numbering and directories required for a single-particle reconstruction project to be managed from a simple GUI (see Section 19.8.4; Baxter *et al.*, 2007).

(v) *PubSub*: a set of Perl programs that enable *SPIDER* procedures to be run in parallel on a computer cluster.

(vi) *SPIDER* documentation: an extensive collection of more than 800 HTML-based documents.

The system is available in versions for Linux, AIX and OS X. Both source code and precompiled binaries for popular platforms are provided. *SPIDER* is available for free download as a GPL Open Source distribution. Its documentation is available under a Creative Commons Attribution 2.5 Licence.

19.8.2. Basic philosophy of single-particle reconstruction

'Single-particle reconstruction' is the term used for the reconstruction of a biological macromolecule from images of a specimen in which the molecule exists in many 'copies' in the form of single isolated particles, *i.e.* with no contact with neighbouring molecules. Since there is no need for crystallization, there is in principle no restriction on the kinds of macromolecules that can be reconstructed, except that they must be above a critical size required for accurate alignment. Combined with cryogenic electron microscopy (cryo-EM), the method is capable of visualizing molecules in their native states. Although the method was originally conceived for a homogeneous population, the introduction of powerful classification techniques is now allowing heterogeneous populations to be disentangled and represented by a series of reconstructions which, suitably ordered, may reflect the development of a system of interacting molecules (a molecular machine) over time.

Each particle image is interpreted as a noisy projection of the three-dimensional Coulomb potential representing the molecule, which is, for practical purposes, identical to the electron-density distribution rendered by X-ray crystallography. The noise (signal-to-noise ratio $\simeq 0.1$) is due mainly to the low exposure required to avoid radiation damage. For reconstruction, all projections must be placed in a common coordinate frame. Since, unlike the case in electron tomography, the angles are initially unknown, the most challenging and computationally intensive task in single-particle reconstruction is the determination of particle orientations, usually done in an iterative manner with increasing angular resolution. In the following, it is assumed that a reference density map of a closely related molecular complex is already available. For instance, a map of an empty ribosome may be used as reference for a data set obtained from a ribosome complexed with EF-G, mRNA and tRNA. For *ab initio* reconstructions of an unknown structure, random-conical and common-lines techniques are available (see Shaikh *et al.*, 2008).

Owing to the oscillatory behaviour of the contrast transfer function (CTF), an entire defocus series must be collected in order to cover the whole range of information in Fourier space. For each micrograph, the defocus is determined by computing the power spectrum and matching it with the CTF. Two strategies are in use in the field: CTF correction is done either at the stage of the raw micrograph, by phase flipping and pooling all data for

reconstruction, or by pooling data into groups with a narrow defocus range, which are then separately reconstructed and combined at the very end using CTF correction by Wiener filtering (Penczek *et al.*, 1997). Although both strategies can be readily realized in *SPIDER*, the one most thoroughly tested and proven is the latter, sometimes referred to as defocus group reconstruction.

For a step-by-step description of the processing path, we refer to the flow diagram in Fig. 19.8.2.1. After defocus determination, particles are selected and aligned to a set of reference projections using rotational and translational cross-correlation. Eulerian angles yielding the highest cross-correlation are assigned. Next, the data are pooled into defocus groups, defined by the range of allowed defocus variation within each group. The range needs to be small enough to avoid resolution loss. Reconstruction of each defocus group yields a preliminary density map. These density maps are merged by CTF correction *via* Wiener filtering, yielding an initial CTF-corrected reconstruction. This reconstruction is then used as the reference in the first angular refinement of defocus group reconstructions, which follows the same principle as the initial alignment. Several cycles of angular refinement are used with progressively smaller angular steps, from the initial ~15° to 0.5° or even 0.2°. From a certain point on, comparisons are only done within a narrow cone of the previous Eulerian angle assignment for a given projection. The progress of the refinement is monitored by computing the Fourier shell correlation at each stage and by following the statistics of angle reassignment, watching for evidence of stability.

For supervised classification, not one but two three-dimensional references are used in the projection alignment (Fig. 19.8.2.1), and the assignment of the class and set of Eulerian angles is done according to the parameters of the reference projection producing the highest cross-correlation coefficient. For example, ribosome data may be split on the basis of inter-subunit ratchet rotation, by presenting 'ratcheted' and 'non-ratcheted' ribosomes as references.

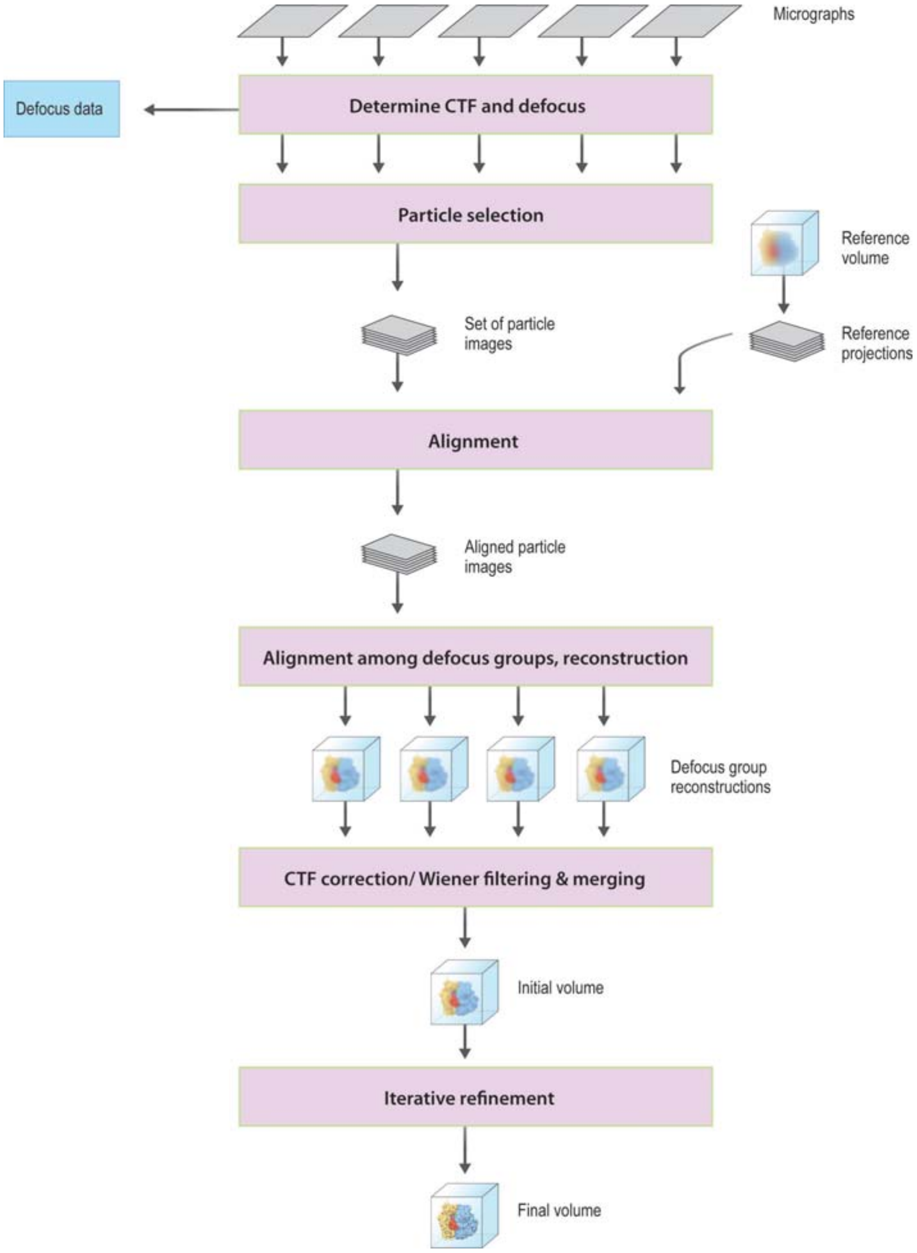

Figure 19.8.2.1

19.8.3. Implementation of single-particle reconstruction in *SPIDER*

The implementation of the reconstruction strategy presented in the flow diagram (Fig. 19.8.2.1) makes use of the modular features of *SPIDER* and its hierarchical calling structure (Fig. 19.8.3.1). The computational task of the entire project (level 4, or uppermost in the hierarchy) can be visualized as being composed of building blocks (level 3), each representing a subtask, such as image alignment, defocus determination, angular refinement *etc.* Each of these building blocks is realized by either a set of elementary commands (level 1) or procedure files containing such commands (level 2). In the reconstruction task, examples of procedures are `deffsc.spi` and `ctf.spi`, which compute the resolution of each defocus group and apply CTF correction, respectively. On the uppermost project level, all data file names, directories and values of parameters must be specified, while the input for lower-level procedures can be variables whose value is not known until the time of execution.

19.8.3.1. Level 1: elementary commands

Commands in *SPIDER* consist of a short two-to-three letter operation mnemonic and a variable sub-option mnemonic. For example, `BP CG` invokes a program performing back-projection reconstruction using a conjugate gradient algorithm. In the interactive on-line mode, commands are entered at a prompt and the system responds with a series of subsequent prompts for more input specific to the operation the command invokes. In the off-line batch mode, relevant in the context of time-consuming reconstructions, both commands and subsequent inputs are placed in a batch or procedure file in the expected order for successive execution.

Figure 19.8.4.1
A *SPIRE* form, displaying the parameters, input files and output files of a *SPIDER* procedure file. The user can edit the values in the white entry boxes or browse for files (*e.g.* by clicking on the 'noise file' button). The changes can either be saved to update the procedure file or executed in *SPIDER* immediately ('Save' and 'Execute' buttons).

There are over 400 different computational operations and sub-operations available in *SPIDER*, which can be grouped into the following categories:

(i) *File handling*: copying, format converting, montaging, stacking.
(ii) *Real-space image manipulations*: alignment, centre-of-gravity computation, contouring, contrast adjustment, edge detection, filtering, histogram computation, masking, mirroring, montaging, peak search, rotation, scaling, segmentation, thresholding, windowing.
(iii) *Fourier-space image manipulations*: autocorrelation, cross-correlation, CTF correction, Fourier filtering, Fourier interpolation, Fourier transformation, resolution determination.
(iv) *Statistical analysis*: averaging, classification of image sets, multivariate data analysis.
(v) *Three-dimensional reconstruction*: algebraic reconstruction technique (ART), constrained simultaneous iterative reconstruction technique (SIRT), projection, SIRT, weighted back-projection.

19.8.3.2. Level 2: procedures

The modular design of *SPIDER* allows incremental development and flexibility by allowing the user to write scripts in the form of procedure files. Procedures containing sequences of commands can be executed just like single commands. Procedures have their own name space, can pass arguments to other procedures and can request input during an interactive *SPIDER* session.

A single-particle reconstruction project requires the application of many complex operations on perhaps several hundred thousand images, in a 30- to 40-step process that involves branching and decision making. To handle these tasks, the scripting facilities of *SPIDER* include commands for conditional expressions, iteration over numbered file names and document manipulation.

SPIDER stores and retrieves numerical results in document files. These are keyed sequential text files containing a table of values, and are used to permanently store items such as image shift coordinates, rotation angles and particle numbers. These values can be retrieved

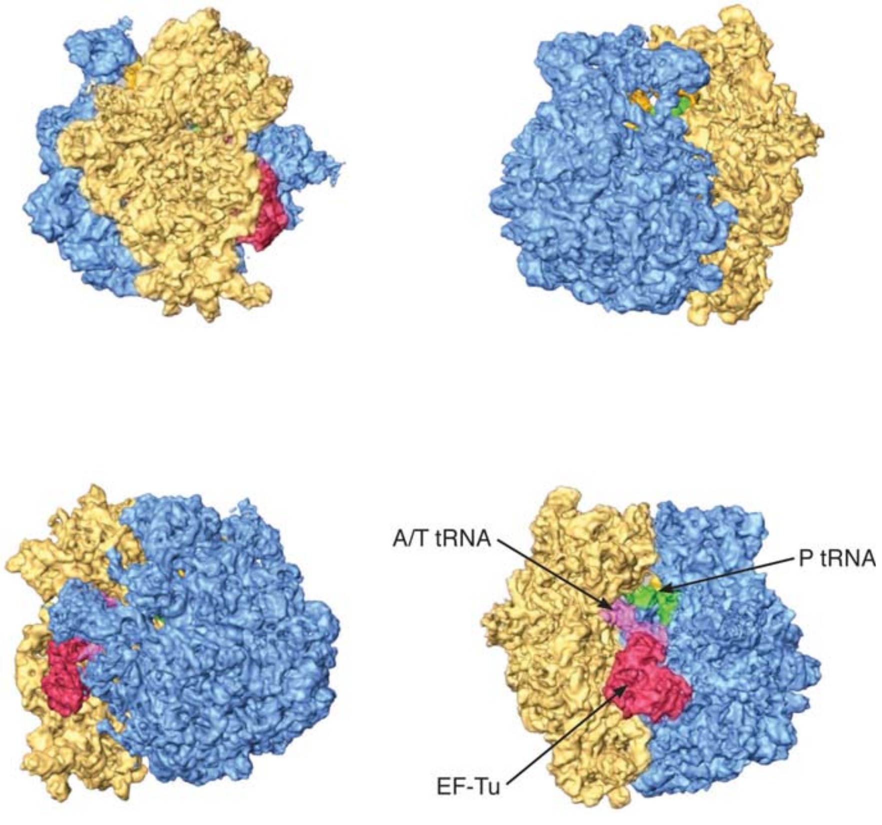

Figure 19.8.5.1
Reconstruction of the *E. coli* ribosome bound with the Phe-tRNA·EF-Tu·GDP ternary complex at 6.7 Å resolution, obtained by the protocol outlined here (LeBarron *et al.*, 2008).

by different procedures or even subsequent *SPIDER* sessions.

There are over 30 document and scripting operations in *SPIDER*:

(i) *Document operations*: retrieve values, select items, sort document, store values.

(ii) *Scripting operations*: assign numerical variables, assign string variables, capture values from *SPIDER* operations, check numerical values, carry out conditional execution and looping, evaluate mathematical expressions, make file enquiries, pass values to/from procedures, set global switches.

19.8.4. Implementation of single-particle reconstruction in *SPIRE*

SPIRE (the *SPIDER* reconstruction engine) is an interactive GUI for managing a *SPIDER* reconstruction (Baxter *et al.*, 2007). A project of single-particle reconstruction may involve dozens of procedure files, each of which may contain hundreds of individual *SPIDER* operations. Procedures usually read *SPIDER* input files (images, volumes or text document files), carry out some processing and write out new *SPIDER* files. The outputs of one procedure are the inputs of the next, and perhaps of other procedures further down the processing stream. Hundreds of thousands of files may be generated during the course of a project.

SPIRE was developed to manage the numerous procedures and data files involved in a *SPIDER* project. As each procedure is executed, *SPIRE* keeps track of the output files generated and adds them to a project database. Users can run the same procedure several times, changing input parameters, and each 'run' is given a unique identification number by *SPIRE*. *SPIDER* is executed in a controlled environment by *SPIRE*, in which error conditions can be trapped and appropriate messages displayed to the user. Successful runs are added to the project database. *SPIRE* provides a graphical interface to these tasks, allowing the user to make changes to the inputs and outputs of a procedure in a displayed form (Fig. 19.8.4.1). Project-wide parameters used by multiple procedures are also graphically viewable and editable. The project database has a spreadsheet-like interface, which can display *SPIDER* images, volumes and stack files in Jweb, as well as text documents in a user-specified editor. Procedure files can be edited, new procedures may be added to a project, and the way a procedure is displayed can be changed.

Projects are represented in *SPIRE* by configuration files. These are text files that use XML tags to specify content, such as the order of procedure files and the directory structure of a project. *SPIRE* provides a configuration editor to manipulate configurations, and thus the overall structure of a *SPIDER* project. If there is a laboratory database system, *SPIRE* provides some capability to upload project results using SQL commands. Finally, *SPIRE* allows the user to write the project file to disk in HTML format, so that a web browser can be used to find out when batch files were run and which data files were generated during the project. *SPIRE* is written in the Python programming language; for graphics it uses the Tkinter module (the interface to the Tk library).

19.8.5. Conclusion

SPIDER was designed to allow high versatility in the design of program flow, so the protocol presented here and in the article by Shaikh *et al.* (2008), which has been used successfully in many applications (for a recent example, see Fig. 19.8.5.1), can be readily changed to meet the challenges of a new project by users who have received a modest amount of training. The same goes for the implementation of alternative strategies, such as CTF correction of raw data, which is beyond the scope of this chapter.

19.9.1. Introduction

During the 1950s and 1960s the electron microscope became a routine research instrument. Many biological structures we now take for granted, such as the ribosome (Chemistry Nobel Prize 2009, see www.nobel.se), were first discovered using the electron microscope. An avalanche of such discoveries emerged after the appropriate preparation techniques for biological specimens were developed, such as the contrasting of molecular complexes with heavy-metal salts (Brenner & Horne, 1959). This dry ‘negative-stain’ approach, however, can also create structural deformations of the sample, hampering its detailed analysis. The introduction of the vitreous water (‘vitreous ice’) specimen preparation technique by Jacques Dubochet and co-workers (Adrian *et al.*, 1984) represented a huge improvement in structural preservation for biological specimens in the harsh vacuum environment of the electron microscope. Notwithstanding the contributions made to the cryo-electron microscopy (cryo-EM) field by the data-processing methodology and software – the subject of this chapter – it was the vitreous ice specimen preparation approach that marked the future success of single-particle cryo-EM. For all practical purposes, vitreous ice is water and the first electron images of virus particles trapped in their native solution state were spectacular (Adrian *et al.*, 1984). The vitreous ice preparations can trap the molecular complexes in full action, in different conformational states, and may represent a window into the detailed functioning of the complexes in their natural environment.

Structural analysis by single-particle cryo-EM is therefore very different to that carried out by traditional X-ray crystallography. With the latter technique, the data collected are diffraction intensities, necessarily reflecting already *averaged* contributions from all unit cells in the crystal. Any information relating to the behaviour of individual molecules is thus lost during data collection. Single-particle cryo-EM, in contrast, is unique in that it preserves the identity of each individual molecular image registered in whatever structural state it happens to be. The marked difference with X-ray crystallography is that the information about each individual molecule or complex is explicitly available in digital form, albeit strongly deteriorated by noise. This also means that in cryo-EM all averaging takes place in the computer; the computational requirements of cryo-EM therefore exceed those of X-ray crystallography by orders of magnitude.

The intrinsic heterogeneity of cryo-EM samples was originally known as the curse of cryo-EM because it degrades the quality of the resulting average structures. Many structures simply would not refine to a reasonable resolution [for reviews of the single-particle methods see van Heel *et al.* (2000) and Frank (2006)]. In recent years, however, heterogeneity has been seen more as a blessing, since, with the appropriate advanced data-processing technology, it is now possible to separate the different conformations of the complex into individual three-dimensional structures. Each of these three-dimensional structures may reveal a different state of the biological complex, as was first shown with a mixture of functional states of the *E. coli* 70S ribosome in complex RF3 (Klaholz *et al.*, 2004). For recent reviews on the challenges posed by heterogeneous biological samples, see Leschziner & Nogales (2007) and Spahn & Penczek (2009). These fascinating new developments build upon almost four decades of advances in software instrumentation, which started in the mid-1960s (DeRosier & Klug, 1968). We here review recent developments of the *IMAGIC* system aimed at optimally processing large heterogeneous ‘four-dimensional’ (4D) cryo-EM data sets to high resolution.

19.9.2. The *IMAGIC* software system

The *IMAGIC* software system (van Heel & Keegstra, 1981; van Heel *et al.*, 1996) is the result of over 30 years of continuous developments, including various major redesign phases. It was one of the first software packages in electron microscopy and many now-standard procedures were pioneered in *IMAGIC*, including surface rendering, multivariate statistical analysis (MSA), automatic classification, projection matching, angular reconstitution, automatic particle selection *etc*. The basic file format of *IMAGIC* consists of a header file, to hold image parameters and processing information, and a separate file holding all actual image data. This ‘stack’ format can hold millions of individual molecular images and all *IMAGIC* programs are designed to loop over all the images in the stack (van Heel & Keegstra, 1981). Users are not burdened with the task of formulating loops over the two-dimensional images needing the same treatment.

The *IMAGIC* philosophy is to create specialized high-level programs for all more complicated tasks. High-level programs allow much better interactive guidance for the user than do image-processing scripts (which are operating-system dependent). A unique feature of all *IMAGIC* programs is that all user interaction is concentrated in a ‘user interaction block’ (UIB). Whether interactively processing images or creating a large ‘batch job’ for later processing, the user always communicates with the program’s UIB with all interactive guidance available (each question comes with its own interactive help). The *IMAGIC* system is available for the most popular current operating systems including Linux, Windows XP/Vista/7 and Mac OS-X.

19.9.3. *IMAGIC* ‘4D’ processing/data format

Recently, another major overhaul of the system was undertaken in order to better handle three-dimensional structural heterogeneity. The relevant *IMAGIC* programs can now loop over entire three-dimensional volumes (and not just two-dimensional images) allowing programs to tackle problems at a much higher level of complexity. About 25 years ago, a radical redesign of the system allowed small two-dimensional images to reside ‘in core’ (the main memory of the computer) rather than on disk, facilitating all alignment algorithms. The new redesign allows whole

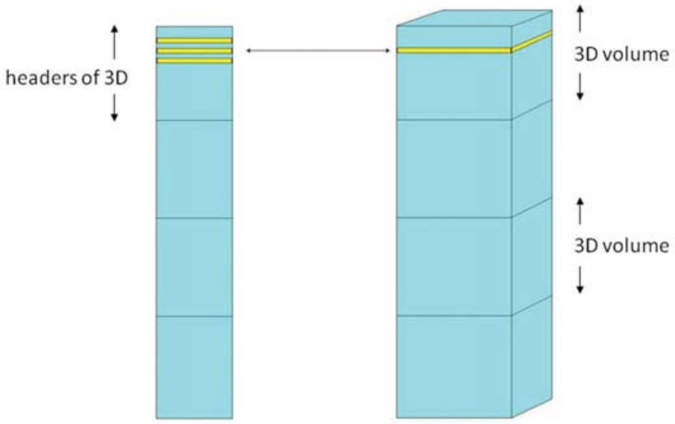

Figure 19.9.3.1
IMAGIC 4D file format. The 4D file format is not very different to the original file format with one header record per 2D image in a stack (van Heel & Keegstra, 1981). The main difference is that specific header locations now indicate the additional organization of a sequence of 2D images in the stack belonging together in a 3D volume. Substantial changes were required in the software, however, to make programs loop over the 3D volumes in one 4D *IMAGIC* file in the way that the programs looped over the 2D images in a stack. For full format details, see www.imagescience.de.

three-dimensional volumes to remain in core and to be manipulated efficiently by single subroutine calls without I/O (input/output) overhead. The file format for '4D' processing has hardly needed any updating other than defining some new header parameters. The reason is that a stack of three-dimensional (3D) volumes (a '4D' data format) is still just a stack of two-dimensional (2D) images, the traditional *IMAGIC* data format (Fig. 19.9.3.1). This '4D' upgrade, however, did require a radical overhaul of all programs, since all relevant programs needed an extra loop over a set of 3D volumes. At the same time, these 3D programs have all become much faster, more compact and more easily maintained because they rely on the new in-core 3D libraries and are now freed of all excess I/O calls.

19.9.4. Software parallelization

In cryo-EM all averaging and information extraction from all individual molecular images takes place *in silico*; the computational requirements are thus huge. Computers are never fast enough for the most demanding single-particle approaches. Over the last 15 years much emphasis has been placed on the parallelization of critical *IMAGIC* code (van Heel *et al.*, 2000), mainly using a message passing interface (MPI; Gropp *et al.*, 1994) to take advantage of modern 'cluster' computing environments. Other software packages have since followed the same parallelization path (Smith & Carragher, 2008). The *IMAGIC* software is implemented such that the same code will run on all machines from a single-CPU notebook computer up to large cluster systems with hundreds of CPUs.

Recently, a 'GPU' library (see www.nvidia.com/object/cuda_home.html) has been implemented in *IMAGIC* to exploit the properties of cheap graphic processors. However, for most 'standard library' operations, like 2D fast Fourier transforms, which can be almost directly linked to existing programs, most time gained in GPU processing is still lost in transporting data to and from the limited memory of the GPUs. The question is whether the time invested in software development for exploiting specific properties of any specific parallel computing hardware will pay off in the longer term for the specific needs of cryo-EM. In the case of the GPUs, the amount of memory typically available per GPU core is rather low.

19.9.5. Full 2D (parallel) astigmatic contrast transfer function correction

The *IMAGIC* contrast transfer function (CTF) estimation and correction programs (van Heel *et al.*, 2000) have recently been upgraded to work fully in two dimensions, enabling the accurate detection of all CTF parameters including astigmatism. This has been carried out in order to accomplish two goals. Firstly, the programs are now capable of operating on an entire data set of charge-coupled device (CCD) images or patches of micrographs. This now allows the use of the parallel MSA programs (see below) to classify sets of amplitude spectra (and create class averages thereof) prior to the precise determination of the defocus and astigmatism parameters. This enables the simple and largely automatic determination of CTF parameters, and subsequent CTF correction *via* phase flipping of entire data-set stacks. Secondly, the ability to accurately detect even extreme levels of astigmatism enables the use of highly astigmatic images, unlocking extremely close-to-focus defoci in order to push the achievable resolution. These programs have been used for the processing of a highly astigmatic data set of the *Limulus polyphemus* hemocyanin, resulting in a ~4 Å reconstruction from only 15 000 raw molecular images, corresponding to 60 000 asymmetric units for this $C2$ point-group symmetry structure (Grant *et al.*, 2011).

19.9.6. Parallel automatic particle picking

Parallel processing is of increasing importance for collecting the large raw data sets required for 4D cryo-EM. If we are interested in a structure that represents 1% of all molecular complexes, we need to increase the size of the data set 100-fold in order to achieve the same resolution we had for a monodisperse data set. This implies that we need to be able to rapidly process data sets of the order of 1 Tbyte in size. One of the fastest automatic particle-selection procedures is still one of the oldest ones, based on the local variance (van Heel, 1982) in the raw micrographs or CCD images. It is applied immediately after the full-data-set CTF correction discussed above. Very important for the calculation of the variance image is the choice of the frequency range used for discriminating the presence of a particle with respect to the background. The sensitivity of the approach is approximately as good as that of particle searching using the cross-correlation function (CCF) (Saxton & Frank, 1977). However, like all CCF alignments (see below), the CCF particle picking requires templates and may tend to bias the particle selection towards the references (Boekema *et al.*, 1986; Stewart & Grigorieff, 2004). Modulation-image particle picking is a variant of the original variance image detection (van Heel, 1982) which is based on the local standard deviation rather than the local variance and avoids squaring of amplitudes. This new algorithm is often the method of choice for an unbiased automatic particle selection. Once a reliable first 3D structure has been calculated, the particle-picking program can then look for all possible views in all possible orientations in an extensive stack of input images (the massive calculations involved exploit MPI parallelization).

19.9.7. Parallel multi-reference alignments and reference bias

Large multi-reference alignment (MRA) schemes (van Heel & Stöffler-Meilicke, 1985) have been accelerated by some orders of magnitude with the introduction of MPI parallelization on computer clusters (van Heel *et al.*, 2000), and MRA remains the largest source of CPU needs in single-particle cryo-EM. However, with the recent focus on discriminating between different functional states, the issue of reference bias resurfaces. With the renewed emphasis on avoiding reference bias (Boekema *et al.*, 1986; Stewart & Grigorieff, 2004), 'alignment by classification' of centred molecular images (Dube *et al.*, 1993) has taken on a new emphasis. An especially useful variant is the rotational alignment of the data set with respect to the main symmetry-related eigenvector. This alignment does not bias the data set with respect to specific references, yet it concentrates much of the variance in the data set into the lower eigenimages (van Heel *et al.*, 2009) and thus yields better class averages while using the same total number of eigenvectors. Such new unbiased approaches are still in full development.

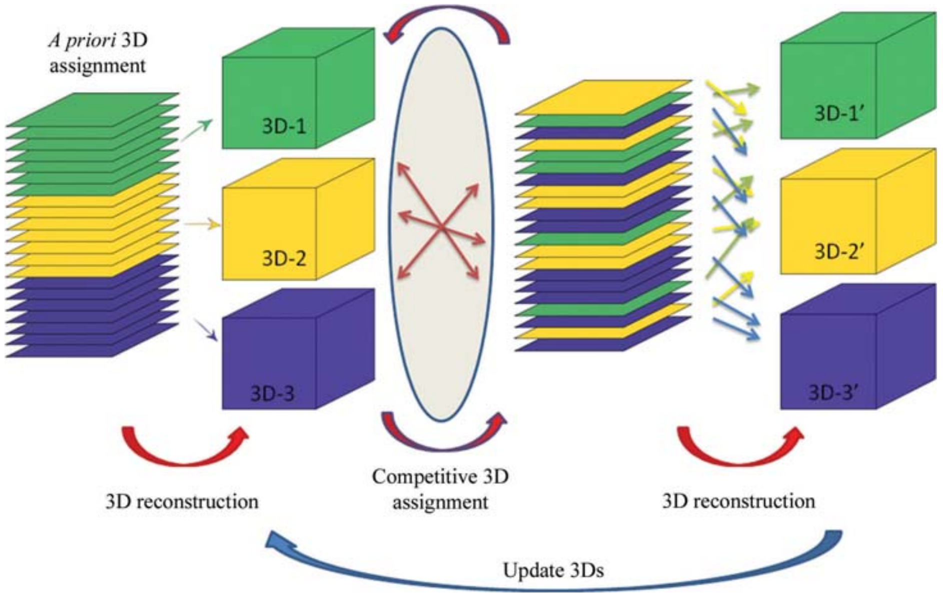

Figure 19.9.7.1
One starts with the (*a priori*) assignment of the images in a stack (original images or class averages) to a number of 3D volumes (named 3D-1 to 3D-3). This assignment can be of various origins: 2D MSA manifold separation; 3D MSA classification; or even a random-number generator, depending on the strategy pursued. Once different 3Ds have been generated, various 'competitive' 3D membership assignment schemes can be applied to the 2D images in the stack. A classical one is multi-reference alignment with respect to re-projections of the different 3D volumes. Another approach is the multi-anchor set Euler angle assignment by 'angular reconstitution' as described in the text. The resulting new 3Ds (named 3D-1′ to 3D-3′) take the place of the earlier 3Ds in this generic iterative refinement scheme. The iterations are stopped once convergence criteria like the Fourier shell correlation (FSC) resolution of the 3Ds reach stability (Harauz & van Heel, 1986; van Heel & Schatz, 2005).

MRAs are now used as a tool in 4D analysis by generating MRA references from a set of 3D structures rather than just a single one (Klaholz *et al.*, 2004; Spahn & Penczek, 2009). Although not different from the 2D versions of MRA, the new *IMAGIC 4D* programs make it simpler to explicitly track a '3D membership' indicating to which 3D volume the best alignment was achieved. The overall administration of the 4D procedures is greatly facilitated, especially during iterative refinement rounds (Fig. 19.9.7.1)

19.9.8. MSA and its parallelization

Multivariate statistical analysis (MSA) was originally introduced to electron microscopy to handle different views of a macromolecule (van Heel & Frank, 1981; Borland & van Heel, 1990; van Heel *et al.*, 2000; Frank, 2006; for an extensive review, see van Heel *et al.*, 2009). MSA approaches are the techniques of choice to structure complex, heterogeneous data sets. Today, a wealth of information on MSA techniques is readily available on the Internet. The highly efficient *IMAGIC* MSA programs are specifically optimized for large data sets: the CPU time required for calculating the main eigenvectors is directly proportional to the total size of the data set. The naive use of standard MSA libraries in most EM software leads to eigenvector/eigenvalue calculations that are proportional to the *square* of the number of images in a data set, making it impossible to process more than a few thousand images (van Heel *et al.*, 2009).

In the first 4D cryo-EM paper revealing different functional states of the same structure (Klaholz *et al.*, 2004), the MSA separation of the data set into the two states was achieved by a manually supported separation of the two conformers in eigenvector space, each representing a different functional state of the 70S ribosome in complex with RF3. Each functional state of a complex represents a 'manifold' in factor space, and one seeks to separate the different manifolds in an unambiguous way, possibly by weighting the eigenvectors (van Heel, 1984; Elad *et al.*, 2008). An alternative is to use the MSA programs to explicitly analyse large sets of 3D volumes in the way one traditionally analyses large sets of 2D images (see van Heel *et al.*, 2009).

The ever-increasing size of the data sets posed a new problem: the MSA processing of large data sets containing, say, a million images (totalling, say, ~1 Tbyte) takes months to process on a single CPU. An MPI parallelization project was undertaken to speed up the eigenvector/eigenvalue calculations. This required parallelization of not only the pure computations but also the I/O operations, since the algorithm reads the large input data sets many times (~30 times) in order to iteratively refine towards a stable answer, leading to I/O bottlenecks (van Heel *et al.*, 2009). Like all other programs mentioned in this chapter, the parallel MSA program is now part of the normal *IMAGIC* distribution.

19.9.9. Handling multiple 3D reconstructions in parallel

A new parallel 3D reconstruction program was created based on the earlier ex-core program implementing the 'exact filter' algorithm (Harauz & van Heel, 1986). With all 3D reconstructions now organized in in-core subroutines, the new program is organized to loop over many 3D volumes and to generate whole series of 3D reconstructions using new options. It is an ideal tool for generating (large) 4D data sets as needed, for example, for the 4D MSA approaches. It is a perfect match for the 4D MRA (above) and the 4D angular reconstitution programs (Fig. 19.9.7.1).
